Foreword

The U.S. Environmental Protection Agency (EPA) is charged by Congress with protecting the Nation's land, air, and water resources. Under a mandate of national environmental laws, the Agency strives to formulate and implement actions leading to a compatible balance between human activities and the ability of natural systems to support and nurture life. To meet this mandate, EPA's research program is providing data and technical support for solving environmental problems today and building a science knowledge base necessary to manage our ecological resources wisely, understand how pollutants affect our health, and prevent or reduce environmental risks in the future.

The National Risk Management Research Laboratory (NRMRL) is the Agency's center for investigation of technological and management approaches for preventing and reducing risks from pollution that threaten human health and the environment. The focus of the Laboratory's research program is on methods and their cost-effectiveness for prevention and control of pollution to air, land, water, and subsurface resources; protection of water quality in public water systems; remediation of contaminated sites, sediments and ground water; prevention and control of indoor air pollution; and restoration of ecosystems. NRMRL collaborates with both public and private sector partners to foster technologies that reduce the cost of compliance and to anticipate emerging problems. NRMRL's research provides solutions to environmental problems by: developing and promoting technologies that protect and improve the environment; advancing scientific and engineering information to support regulatory and policy decisions; and providing the technical support and information transfer to ensure implementation of environmental regulations and strategies at the national, state, and community levels.

This publication has been produced as part of the Laboratory's strategic long-term research plan. It is published and made available by EPA's Office of Research and Development to assist the user community and to link researchers with their clients.

Abstract

This report describes feasibility tests of a two-step strategy for air pollution control applicable to exhaust air contaminated with volatile organic compounds (VOCs) from painting aircraft. In the first step of the two-step strategy, the VOC-contaminated exhaust air passes over coated, polypropylene, hollow-fiber membranes while an involatile organic liquid (silicone oil, mineral oil, decanol, octanol) is pumped counter-current through the fibers. The organic liquid captures the VOCs, and their concentration in the circulating liquid increases whenever exhaust air circulates. In the second step, the circulating organic liquid loop passes through a second set of hollow-fiber membranes that support a culture of microorganisms, which remove and metabolize the VOCs, on their exterior surfaces. The concentration of VOCs in the circulating liquid loop oscillates as the painting process starts and stops because VOC capture by the liquid is a fast process whereas removal and metabolization by microorganisms is a slow process. Despite constraints caused by limited availability of commercial membrane packages, adequate rates of removal and transport into and out of circulating octanol were shown to be adequate to support the proposed technology. Biodegradation was also qualitatively validated, although each of the organisms used in these tests selectively metabolized specific classes of solvents; however, other cultures or sequential treatment stages are expected to provide satisfactory removal. Scale-up revealed material incompatibility of the membranes and adhesives with octanol. Silicone oils and vegetable oils were briefly tested as the circulating organic liquid at the end of the project. Pressure drop also remains as an engineering challenge unless ventilation exhaust rates are decreased.

Acknowledgments

This research was supported by the U.S. Department of Defense through the Strategic Environmental Research and Development Program (SERDP). This report was prepared under Contract Number 68-C-99-201 for the U.S. Environmental Protection Agency (EPA), Research Triangle Park, NC.

This final report describes work performed from 1 March 1998 to 30 January 2001. The Co-Principal Investigators were first Norman Kaplan then Jack Wasser of EPA's National Risk Management Research Laboratory (NRMRL) and Dr. Joe Wander of the Air Force Research Laboratory (AFRL/MLQ).

The authors particularly acknowledge the contributions and guidance of Bradley Smith and Dr. Robert Holst of the SERDP Program Office and the review panel members, without whose help this study would not have been possible.

Executive Summary

A. Objective

The objective of this project was to examine the feasibility of capturing and destroying volatile organic compounds (VOCs) from process or storage exhaust air by extracting the VOCs through a coated, hollow-fiber membrane into an involatile liquid and then metabolizing them with bacteria residing on the exterior surface of a second, coated, hollow-fiber membrane.

B. Background

1. VOC Emissions from Large Aircraft-Painting Facilities

Implementation of the Clean Air Act in the form of the National Emission Standards for Hazardous Air Pollutants for aerospace coating operations (Aerospace Manufacturing and Rework Facilities NESHAP) imposed a requirement that large aircraft-painting operations either apply an emission control system to decrease the amount of VOC emitted to the atmosphere by at least a threshold amount (originally 81 percent) or apply coating materials that contain less than a specified (for each) threshold amount of VOCs. Strenuous efforts to develop competent low-VOC coatings have not been uniformly successful, and use of these compliant coatings generally involves compromises in coat quality and durability and in preparation, application, and curing time and effort.

By most standards, the option to control emissions is by far the superior approach because it preserves availability of coatings that have been optimized after decades of development and experience, because it involves no changes to the established painting methods and techniques, and because the amount of VOCs emitted are less than half that from an equivalent operation conducted with low-VOC coatings. However, ventilation of an aircraft-painting facility makes inefficient use of air by continuously ventilating the entire volume of a hangar while painting is conducted intermittently in a much smaller part of it, so the exhaust volume is large and the level of contamination is low. Both factors act to drive up the cost to decontaminate these exhausts by conventional VOC control methods.

The Strategic Research & Development Program (SERDP) issued Statement of Need CP-98, VOC Control Technology for Aircraft Painting and Depainting Facilities as a call for development and evaluation of alternative technologies that, alone or in combination with flow-reduction technologies (e.g., exhaust recirculation), would decrease the cost to control emissions of VOCs from aircraft

painting operations. Heat generation and loss in processes handling flow rates approaching 1M ft³/min is commonly the main source of cost, fuel consumption, and greenhouse gas and airborne pollutant generation. As efforts to oxidize organic vapors by catalysis at low temperatures have found success only with such easily oxidized materials as aldehydes and thioethers, the most-promising avenue of development is through concentration of the VOCs prior to destruction. Recovery is possible as well but rarely economical for gross mixtures of solvents.

2. Membrane Extraction and Biotreatment

With appropriate modification of the structural polymeric surface, hollow-fiber membranes (HFMs) allow selective passage of molecules based on their physical properties. Significant research has examined separation and biotreatment of VOCs from air streams with varying degrees of success. A literature search performed during this project led to several pertinent conclusions regarding membrane configuration, materials of construction, extraction fluid, module operation and control of biofouling. These conclusions are summarized as follows:

1. Hollow fiber shell-and-tube membrane modules offer the highest possible surface-area-to-volume ratio, roughly an order of magnitude more than the nearest alternate, the spiral-wound configuration.
2. Asymmetric, composite membranes composed of a highly porous support membrane coated by a thin, nonporous, permselective film offer the most effective combination of perme-ability and selectivity.
3. For gas-liquid systems, it is most efficient to have the coating film contacted by the liquid phase and the pores filled by the gas. For instances where the coating film is the predominant mass transfer resistance, the fluid that fills the pores is less important.
4. The composition of the coating film is critical to performance. In decreasing order of permeability to organic vapors, it was found that poly[(1-trimethylsilyl)-1-propyne] (PTMSP) is greater than polydimethylsiloxane (PDMS) which is greater than polyalkylsulfone (PAS-16), other rubbery polymers are greater than fluoropolymers. Although PTMSP exhibits the highest permeability to organic vapors, its performance decays relatively rapidly over time, so it is not considered suitable for long-term commercial applications. PDMS is a rubbery polymer that, along with other silicone rubber derivatives, is the material of choice by researchers involved in organic vapor separations. PAS-16 is relatively uncharacterized but offers excellent properties as a rubbery polymer with local crystallinity.
5. Lower temperatures favor organic vapor separations.
6. Removal percentages in excess of 95 percent are possible with membrane extraction systems operated with gas-membrane contact times on the order of 20 seconds.
7. Low-vapor-pressure oils and alcohols (silicone oil, mineral oil, decanol, octanol) exhibit excellent solubility and permeability characteristics for organic vapor separation, with silicone

oil exhibiting optimal performance in composite membranes.

Peretti et al. have filed for a patent for the use of coated HFMs with involatile solvents to capture VOCs from furniture-finishing industries and to biodegrade the VOCs by a process of direct capture across a second HFM by bacteria colonizing the external surface.

Figure E-1 depicts the functional elements and flows in the Membrane Extraction and Biotreatment (MBT) process. Contaminated exhaust gas enters at the bottom left and is stripped of VOCs as it passes upward through an array of parallel HFMs. The stripped exhaust is released to the atmosphere, so the amount of VOC in the treated exhaust is the total amount released, and this amount defines the efficiency of the control device. An involatile solvent circulates inside the HFMs opposite to the direction of airflow, so the concentration of captured VOCs increases downward to the point of entry of the facility exhaust before entering the bottom of the membrane bioreactor (MBR).

Figure E-1. MBT System Schematic

The MBR is a similar array of parallel HFMs surrounded by a nutrient medium circulated downward among the HFMs to sustain a culture of microorganisms adhering to their surface. The solvent and its load of VOCs rises inside the HFMs while the microorganisms capture and consume part of the VOCs. During periods of painting, VOCs will enter the system faster than the microorganisms can

consume them. The stripping fluid storage tank is a reservoir of fluid with an unreacted VOC concentration that increases gradually during painting and subsides during interludes between painting episodes. This distribution of peak load serves both to decrease the size of the MBR and to ensure a fairly constant rate of delivery of VOCs to the MBR.

Operating equations were derived to describe the membrane separation processes for a system with non-coated hollow fibers and using octanol as the stripping fluid. The final result for the separation/concentration unit was a design equation that relates concentration, partition coefficient, membrane surface area, and flow rate to an overall mass transfer coefficient, K_o . The K_o is based on the overall system driving force and is defined by a sum of resistances model. In the equation shown below for K_o in the separation/concentration unit, the concentration (C) subscripts A and O denote the air and octanol phases, and subscripts 1 and 2 represent inlet and outlet conditions, respectively. P is the air/octanol equilibrium partition coefficient, Q is the volumetric flow of the respective phases (cubic centimeters per second), and A_m is the membrane surface area (square centimeters).

$$K_o = \frac{\ln \left(\frac{\frac{C_{A2}}{P} - C_{O2}}{\frac{C_{A1}}{P} - C_{O1}} \right)}{A_m \left(\frac{1}{Q_o} - \frac{1}{Q_A P} \right)}$$

Experiments were initially conducted using individual pure VOCs that are typical components of paints to assess mass transfer rates and removal efficiencies. Studies progressed to include VOC mixtures and real military paint. Degradation of VOCs was measured for individual and mixed biofilm cultures. All of these experiments were necessary because both the separation and biotreatment processes are competitive among the species present.

C. Scope

This is the final technical report for SERDP project CP-1105, Membrane-Mediated Extraction and Biotreatment of VOCs. Results of the first half of the project have been presented at two national meetings. The associated long abstracts published in the respective meeting proceedings are included as Appendixes D and E.

D. Methodology

Initial evaluations of mass transfer coefficients for the membrane module were conducted by quantifying the removal of each individual VOC [*m*-xylene, toluene, methyl ethyl ketone (MEK)] from an air stream. Experiments were performed to determine the effect of airflow rate, stripping fluid flow rate, air stream VOC concentration, and stripping fluid VOC concentration on overall mass transfer coefficients. This early work was performed using the Celgard Liqui-Cell module. The focus of the separation/concentration process development was aimed at producing a module that provided high-efficiency removal of VOCs from the airstream at high air flow rates and low pressure drop.

E. Test Description

Numerous biotreatment experiments were conducted to determine efficacy of the proposed biotreatment module for enhanced VOC removal from the stripping fluid. These studies included the following:

- Screening experiments to identify organisms able to degrade paint VOCs
- Liquid-liquid stripping efficiency of MEK with and without a biofilm present
- Degradation of individual and mixed VOCs with individual and mixed organism biofilms
- Growth of degraders and degradation of single and mixed VOCs to determine strain characterization, substrate range, metabolic regulation, and organism interactions
- Capacity of dual organisms in staged reactors to degrade mixtures of differently soluble VOCs

F. Results and Discussion

The Celgard Liqui-Cell membrane module, or contactor, was used in the early bench-scale experiments. Because of the difference in pressures between the air and stripping fluid sides of the HFMs, some leakage of stripping fluid into the air occurred. Because it is not economically feasible to pressurize the air side to prevent this leakage, the application of a thin coating of a VOC-permeable coating to the HFMs, preferably on the inside of the fibers to maximize mass transfer was considered. Acceptable coated fibers and modules were not commercially available, and work with a number of vendors to provide a suitable contactor proved to be unsuccessful. An in situ coating technique for the Celgard contactor was developed but was found to be too time consuming as a cost-effective approach.

A secondary issue regarding cost-effective contactor design was the relatively high pressure required to drive the air through the Celgard module. Discussions were held with module vendors to develop an efficient separation/concentration module with non-porous coated fibers and low pressure drop. Applied Membrane Technologies (AMT) was selected to provide a cross-flow module design with fibers externally coated with plasma-polymerized silicone rubber. The coating was found to perform

adequately, but the fibers themselves elongated when exposed to the octanol stripping fluid. This led to the substitution of silicone oil as the stripping fluid. Upon developing a feasible module design, pilot testing was performed to validate its performance.

Two basic sizes were tested. Bench scale tests using 1 and 2 modules were done using the Celgard microporous hollow-fiber membrane module coated with perfluorodimethyldioxole and tetrafluoroethylene (PDD-TFE). Pilot scale studies with paint vapors were done using the AMT module coated with silicone rubber in arrangements of 2 and 10 modules. Test flow rates up to 200 cfm provided contact times of less than 0.1 sec with the coated membrane.

In the bench-scale testing, VOC removal rates ranged between 4.4 percent and 73.7 percent. Higher air side flow, lower oil flow, and lower VOC inlet concentrations were generally associated with lower removal rates. Pilot-scale test results were variable and sometimes difficult to understand. Average VOC removal rates were 34–80 percent, while removal of individual compounds ranged from 17 to 82 percent. As in the bench-scale testing, MEK proved to be the most difficult compound to extract from the air. A major problem with the cross-flow modules occurred when leaking modules allowed the fibers to become wetted with the less-viscous silicone oil, causing fiber elongation and subsequent voids between some fibers and matting of others. This resulted in poor contact with the air stream and reduced VOC removal rates. Time and funding limitations prevented actions to address these issues. These problems resulted in a reduction in planned pilot scale stream from 500 cfm to 200 cfm.

G. Conclusions

The membrane-supported biofilm modules successfully removed VOCs from the recirculating stripping fluid stream. Degradation of the aromatic compounds investigated (toluene, *m*-xylene) was achieved; these compounds were not observed in the aqueous phase above the biofilm. MEK biodegradation is problematic, appearing to be partially inhibited by toluene and *m*-xylene. Further studies are required to ascertain the underlying mechanism.

A fully-integrated pilot system was not successfully demonstrated. Although the test results did not meet the research goal of 85-95%, the MBT concept showed potential for being developed into a technically feasible process. However, the MBT concept has been shown to offer several attractive benefits:

- Continuous biotreatment of VOCs directly from the stripping fluid avoids the mechanical complexities of sequential medium transfers found in most concentrate-and-treat designs (e.g., air-to-adsorber-to-lower-volume-air-stream, and thence to final treatment).
- Continuous recirculation of captured VOCs through the biotreatment module provides

complete destruction of captured VOCs.

- Modularity of the MBT unit allows linear scaling of a large system by connection of n units in parallel
- Modularity of the MBT unit allows amplification of the net capture-and-removal efficiency by connection of two or more units in series.

H. Recommendations

Several serious obstacles remain before a practical MBT system can be applied to a painting operation:

- Available materials of construction must be compatible with each other (fiber, coating, assembly adhesives), with the stripping fluid, with the microorganisms, and with the VOCs to be treated.
- Manufacturing techniques for membrane modules must advance enough to allow cost effective fabrication of low-pressure drop, high efficiency, leak-free modules.
- Microbiological cultures must be identified that can coexist and metabolize all of the VOCs to be treated at practical rates.
- Some engineering relief may be possible, but the ventilation system must be able to accommodate a fairly large pressure loss (>25 in. H_2O) across the HFM array, consistent with acceptable process economics.

Additional fundamental and applied research is needed to fill out the understanding of these processes. Design and eventual commercial availability of properly configured and scaled hollow-fiber membrane modules must occur before MBT or related technologies can be implemented on a practical scale. Finally, this technology will be compatible only with processes that can tolerate a moderate pressure (>20 in. H_2O) loss through its control system, for example, low flow high concentration sources.

1.0 Objective

The objective of this project was to examine the feasibility of developing a practical VOC control method using coated, hollow-fiber membranes to extract organic vapors from ventilation exhaust streams into a circulating pool of an involatile liquid and to deliver the organics at a buffered rate to a biofilm adhering to the exterior surface of a separate, coated membrane.

1.1 Background

This project was performed in response to the Statement of Need for FY98 SERDP, Compliance New Start Number 2 (CPSON2), entitled, “VOC Control Technology for Aircraft Painting and Depainting Facilities.” Painting and coating operations present a number of environmental problems and economic challenges. Volatile organic compounds (VOCs) and other hazardous air pollutants (HAPs) are present in all currently used coatings. The toxic compounds include metals, metal oxides, and VOCs. Many of these compounds are either direct or indirect health threats; VOCs are ozone precursors and may be designated as toxic, and many metals and metallic oxides are identified on toxic compound lists. In response to the Clean Air Act Amendments of 1990, VOCs and HAPs in coatings are being reduced, thereby reducing emissions of ozone precursors and toxic compounds from painting operations. However, additional controls are mandated in specific instances, such as aircraft booths. The National Emissions Standard for Hazardous Air Pollutants (NESHAP) specific to aircraft painting will force the DoD to either implement volatile hazardous air pollutant (VHAP) control technology or replace existing coating formulations. Because efforts to develop replacement coatings have met with only mixed success, implementation of control technology appears to be the most-promising near-term solution.

Control technology cost primarily depends on contaminated airflow rates. Paint spray booth exhausts are high-volume streams because an obsolete OSHA standard requiring a minimum velocity of 100 ft/min) through all booth section areas remains in the public record. Conventional booth design approaches include no provision for adjusting flowrate, relying instead on using a high flowrate with clean filters that will remain above the 100-fpm threshold after the filters are dirtied. If controls are required for VOC destruction, the necessary equipment must be sized for the maximum exhaust flow rate. As a result, typical booths emit large volumes of air contaminated with dilute concentrations of VOCs and HAPs. Many current technologies treat the VOCs within the entire gas volume directly, leading to large-volume incineration, absorption, or biofiltration systems. These technologies are extremely expensive in terms of both capital and operating expenses. Also, they often generate hazardous byproduct streams that must be further treated. The system evaluated in this research was designed to both minimize the treated volume and to concentrate the VOCs within that treated volume in order to reduce the size and cost of the ultimate control device. These

advantages would make this VOC treatment option applicable across a broad range of spray booth sizes.

Such a VOC control system could eliminate a significant portion of toxic materials emissions from DoD installations. Past data regarding aircraft service reported in *Air Force Times* indicate that 5 of the top 10 air discharges that triggered Toxic Release Inventory reporting thresholds from 131 DoD installations were typical paint constituents. Significant reduction of these emissions in a cost-effective manner is important to DoD's adherence to the 1995 Aerospace NESHAP for Aerospace Manufacturing and Rework Facilities and to its meeting existing and evolving limits for VOC emissions in ozone nonattainment areas.

1.1.1 Membrane BioTechnology Development Background

During initial Membrane BioTechnology (MBT) development, tests were performed to assess the ability of hollow-fiber membrane contactors to separate VOCs from an air stream. A membrane separation system was constructed to allow contact of VOC-laden air streams with octanol inside a Hoechst-Celanese Liqui-Cel hollow-fiber module. The entire membrane separation system used in initial experiments is shown schematically in Figure 1. A stripping fluid, octanol, was passed through the unit's shell space while air flowed through the fibers. The two phases contacted in counter-current cross flow. The octanol reservoir was recycled to the module, but air passed through the system only once. Air flow rates were varied from 10 to 40 L/min, giving a minimum gas/membrane contact time of 0.004 seconds based on the inside volume of the hollow fibers. The air-side pressure drop ranged from 0.5 to 2.0 psi, and the total surface area available for mass transfer was 1.4 m².

Figure 1. MBT System Schematic

Biological degradation experiments were conducted with naturally occurring microorganisms isolated from soil samples removed from a site contaminated with gasoline. Using a mixed consortium of organisms isolated in liquid culture from soil samples removed from this site, degradability of model compounds from each of the species found in furniture exhaust gases was examined (Table 1). Following completion of these initial studies, organism subcultures were generated for specific compounds. By enrichment of the initial gasoline-adapted consortium in individual flasks with isobutyl acetate (IBA), methanol (MeOH), methyl ethyl ketone (MEK), methyl isobutyl ketone (MIBK), *m*-xylene, and *p*-xylene, respectively, consortia capable of degrading each compound were developed.

<i>o</i> -Xylene *	<i>p</i> -Xylene *

* Indicates compounds common to DoD painting operations

One pure culture, designated MX-2, was established on *m*-xylene and another, PX-2, was established on *p*-xylene. Other consortia which grew on either IBA, MEOH, MEK, or MIBK consisted of approximately three different organisms each. Maximum growth rates for the isolated consortia were determined in shake flask studies containing low-ionic-strength buffer solution supplemented with the appropriate carbon source. Growth rates obtained with *m*-xylene in the presence of additional carbon sources and with pure octanol are given in Table 2.

The partition coefficient is defined as the ratio of concentrations of a given compound in two phases (octanol/air and octanol/H₂O) at equilibrium. Before beginning work with Liqui-Cel membrane modules, partition coefficient experiments were performed to investigate the equilibrium distribution of *m*-xylene, MEK, and MIBK between phases for stripping fluid/air and stripping fluid/aqueous systems. Octanol was chosen as the stripping fluid. Values of the partition coefficient at different temperatures are given in Table 3.

Table 2. Growth Rates of MX-2 with Modified Carbon Sources

Carbon Source	Specific Growth Rate ^a	Degradation Rate ^b
<i>m</i> -Xylene	0.46 hr ⁻¹	3.60×10 ⁻¹⁰ mg/(hr-cell)
<i>m</i> -Xylene + 0.2% MeOH	0.45 hr ⁻¹	3.57×10 ⁻¹⁰ mg/(hr-cell)
<i>m</i> -Xylene + 0.2% EtOH ^c	0.40 hr ⁻¹	2.34×10 ⁻¹⁰ mg/(hr-cell)
<i>m</i> -Xylene + 500 ppm ^d octanol	0.46 hr ⁻¹	3.60×10 ⁻¹⁰ mg/(hr-cell)
500 ppm octanol (no <i>m</i> -xylene)	0.20 hr ⁻¹	not applicable

^a The specific growth rates are reported as the rate of change of cell dry mass divided by the cell dry mass.

^b The degradation rate is the rate of removal of *m*-xylene (in mg per mL of medium per hour) divided by the cell density (in cells per mL).

^c Ethyl alcohol.

^d Mass/mass

Table 3. Partition Coefficient Values

Temp.	Partition Coefficient [octanol]/[air]			Partition Coefficient [octanol]/[water]		
	<i>m</i> -Xylene	MEK	MIBK	<i>m</i> -Xylene	MEK	MIBK
6 °C	9865	2181	NA ^a	NA	NA	NA
22 °C	7978	1634	22,045	NA	NA	NA
31 °	7703	1344	8721	1021	33	2.1

^a NA=not analyzed

Experiments were also conducted to examine the range of compounds degradable by enzymes present in the *meta*- and *para*-xylene-degrading organisms. As shown in Table 4, these organisms successfully removed many compounds that are typically difficult to biodegrade. Higher values for oxygen uptake indicate a compound is being more rapidly degraded.

An additional set of experiments was run to evaluate alternative stripping fluids because commercially available octanol is fairly expensive. Partition coefficients were determined for *m*-xylene in corn oil, sunflower seed oil, and mineral oil at 31 °C. The respective partition coefficients ([oil]/[air]) were 8283, 8244, and 7284, comparable to that of octanol. These oils cost about one-fourth that of octanol.

Table 4. Oxygen Uptake Rates for Various VOCs

Compound	Oxygen Uptake, mmol/min-mg Total Cell Protein	
	Strain PX-2	Strain MX-2
<i>p</i> -Xylene	0.34	1.21
<i>m</i> -Xylene	0.31	0.82
<i>o</i> -Xylene	NA	0.31
Toluene	0.17	0.18
Benzene	0.13	0.27
Styrene	0.47	0.55
Benzoic acid	2.34	0.66
Catechol	5.19	1.23
3-Methylcatechol	1.50	1.17
4-Methylcatechol	4.35	0.92
Protocatechuic acid	0.00	0.32

1.1.2 Treatment Process Concept

In the Membrane BioTreatment (MBT) system, organic volatiles are first separated from the air stream, concentrated, and then completely metabolized by microorganisms. Selective removal and concentration of VOCs from the exhaust stream enables significant reduction in the volume directed to the final control device, dramatically reducing equipment size and costs. The system allows for independent optimization of each process. One process removes organics from the air, and the other process biodegrades them. The system relies on micro-porous hollow-fiber membrane contactors to mediate the extraction and concentration of vapors from the air into an organic stripping fluid and to provide a physical support for degradative microorganisms. A schematic of the MBT system appears in Figure 1.

Exhaust gases laden with VOCs pass first through a particle filter, which removes solid particles and any residual atomized droplets of coatings. Next, the gases enter a membrane separation/concentration (S/C) unit composed of bundles of microporous, hydrophobic fibers. In the S/C unit, vaporized HAPs and VOCs (represented as dark particles) are transferred from the exhaust gases into a stripping-fluid medium (potentially octanol, silicone oil, sunflower seed oil, etc.), as shown in Figure 2. The stripping fluid is chosen to have low volatility, low water solubility, and high (fluid/air) partition coefficients for the VOCs. The medium serves as a pollutant sink and allows accumulation of significant HAP/VOC concentrations.

Figure 2. VOC Extraction in the S/C Unit

Figure 3. Bioextraction of VOCs

Upon exiting the S/C unit, the stripping fluid is delivered to a biomembrane unit. There, the stripping fluid circulates past one side of another microporous membrane with VOC-degrading bacteria in a film on the opposite side of the membrane. Figure 3 illustrates diffusion of VOCs through the membrane pores (filled with stripping fluid) into the biofilm, in which they are selectively and completely metabolized by the bacteria. The solvent is then collected in a storage vessel and ultimately recycled through the S/C. When hydrocarbon pollutants are treated, outputs from the overall MBT System are clean air, carbon dioxide, and a mixture of water and nonhazardous cell mass.

In the design of a full-scale system for a military paint spray booth, further economic gains can be realized by reducing the contaminated air volume through the application of partitioned recirculation. This patented technology was developed through EPA and Air Force funding to reduce the cost of VOC control by minimizing the treated volume. This technology takes advantage of the fact that, in horizontal-flow booths, the lower segment of a paint booth exhaust contains more highly concentrated VOCs, and conversely, the upper segment exhaust contains lower VOC concentrations. This characteristic allows both the recirculation of a significant portion of the exhaust (30 to 90 percent) without adverse health and safety implications, and a comparable reduction in the size of the required VOC control device. Adding on this technology enables a two-step reduction in the volume of VOC-contaminated streams to be treated: first, partitioned recirculation concentrates the VOCs into a smaller air volume; and second, the S/C unit concentrates the VOCs in a proportionally smaller volume of stripping fluid for biodegradation.

MBT offers potential unique advantages due to the nature of the control technology and the impact

of implementation on coating operations. Advantages include the following:

- **High VOC destruction:** Naturally occurring bacteria consume pollutants as food for growth and energy.
- **Non-Pollutant-Generating Process:** MBT is a clean process with no hazardous by-products.
- **Optimized Rates of Removal and Degradation:** Having separate processes for removal and destruction of pollutant compounds allows each to be designed and operated for maximum efficiency, and equipment size is minimized.
- **Adaptability:** MBT is fully adaptable to individual sites. S/C units are modular, which allows the pollutant-removal process to be tailored to site-specific operations, facilities, and regulatory permit requirements. Selection and optimization of suitable micro-organisms ensures effective degradation of site-specific HAPs and VOCs.
- **Extended Equipment Life:** Each module of the S/C units may be changed on an individual basis, and extra modules may be built into the system and/or kept on site to make replacement easier.
- **Operating Flexibility:** The stripping fluid storage vessel allows the MBT system to operate continuously to control intermittent processes. For example, some coating operations are single-shift, resulting in eight hours of waste generation followed by 16 hours of down time. In other instances, painting facilities may be off line for days or even weeks. The storage tank mitigates the interruptions in waste generation—that is, the tank *uncouples waste generation from biotreatment*, which allows the biotreatment process to operate at optimal levels regardless of spray booth schedules. A VOC feedstock can be manually introduced to maintain the bacterial colonies during extended interludes between painting episodes.
- **Cost-Effective Treatment:** Original estimates indicated that this system would be significantly less costly than other typical VOC control systems for medium and large paint spray booths.

1.2 Scope

This is the final technical report describing a 2-year project supported by the Strategic Environmental Research and Development Program [SERDP].

2.0 Technical Objectives

The overall objective of this small, pilot project was to validate and extend development of a potentially cost-effective VOC control system for painting facilities that meets the requirements of the Aerospace Coatings NESHAP—81 percent reduction in VOCs from noncompliant coatings. This was believed to be feasible by combining the partitioned recirculation technique for flow reduction with a novel process that concentrates VOCs for biological treatment. The project was designed as a two-phase activity consisting of bench- and pilot-scale efforts. The objective of the project in phase I was to demonstrate that membrane-supported extraction, coupled with membrane-supported biotreatment, is a technically feasible VOC treatment process for DoD painting emissions. In phase II, the objective was to establish the technical and economic efficacy of this process to treat actual aircraft painting emissions. The original concept was to use the paint booth facilities at Tyndall AFB as the pilot test site, but that option was abandoned after technical difficulties caused delays and added costs. Secondary goals of Phase II included both attention to the effects of particulate fouling on membrane transfer performance and dissemination of information about the technology by identifying all DoD sites and organizations that could benefit from this technology and distributing appropriate technology transfer materials to them.

The original cost estimates for the technology were based on lab-scale performance. In support of project technical objectives and economic feasibility, it was necessary to answer the following critical questions:

1. Under conditions of 85–95 percent reduction of VOC emissions, what are the mass transfer rates of VOCs present in DoD painting and depainting operations (e.g., MEK, MIBK, xylenes, toluenes)
 - a) from air to organic solvent via membrane?
 - b) from organic solvent to aqueous phase via membrane?
2. What are the contact times needed to achieve the above mass transfer rates?
3. Can a membrane-supported biofilm be stably maintained?
4. What are the degradation rates of the above-cited VOCs?
5. Using commercially available membrane units for design purposes, what is the projected cost of treatment in
 - a) dollars per cubic feet per minute of air treated?
 - b) dollars per unit of VOC removal?

The design is to be based on modules capable of controlling streams from 20,000 to 300,000 ft³/min of exhaust treated at typical VOC concentrations found in DoD operations.

6. What is the impact of particle and particle-bound contaminants such as isocyanates on membrane performance? How does this impact filtration requirements?

Answers to these questions were the subject of this project and were necessary to scale-up and design the process and to determine process economics. Preliminary targets for mass transfer rate were 10^{-4} cm/sec for VOCs from air and 3×10^{-10} mg/cell-hr for VOC degradation rate.

3.0 Results at Bench-Scale

Details of progress in the bench-scale development phase (prior to pilot-testing) are described in two publications, “Membrane-Mediated Extraction and Biodegradation of VOCs from Air,” reviewed and accepted 2/25/00, which was presented at the 2000 Spring National Meeting of the American Institute of Chemical Engineers (AIChE), and “Membrane Biotreatment of VOC-Laden Air,” reviewed and accepted 5/1/00, which was presented at the 2000 Annual Conference of the Air & Waste Management Association (AWMA).

3.1 Development of Coated Modules

The project approach outlined in the Work Plan was initiated but was soon altered based on early findings. One significant area of study, which was not the subject of the technical papers, was in situ coating of fibers in Celgard Liqui-Cell modules. Because significant back pressure was required on the air side of the contactors to prevent oil seeping through the pores, it was determined that coated fibers were necessary to make the process cost competitive, but acceptable coated fibers were commercially unavailable. Celgard did not manufacture any contactors with coated fibers, so work continued on testing the performance and ease of application of several coatings on smaller, bench-scale Celgard contactors. Significant effort was aimed at identifying or developing a suitably coated (nonporous polymer coating on a porous polypropylene sub-strate) separation/concentration membrane module. Discussions with Compact Membrane Systems (CMS) led to the acquisition and testing of a module coated on the inside of the lumens (hollow fibers) with an amorphous copolymer composed of perfluorodimethyldioxole and tetrafluoroethylene (PDD–TFE). Although PDD–TFE would not have optimum transfer characteristics, CMS was the only vendor identified and judged to be capable of applying in situ coatings to the inside of the lumens, and they would agree to work with only this material. Methyl ethyl ketone (MEK) and *m*-xylene were the VOCs used to test air to octanol VOC mass transfer performance. Three conditions were examined in duplicate for each compound, for a total of 12 experiments. Air flow rate and VOC concentration were experimental variables while absorbent (octanol) flow was held constant. Experimental conditions were chosen to emulate previous work with a Celgard Liqui-Cel module containing hollow fibers coated on their outside surface with PDD–TFE. The results of the tests (see Table 5) were similar to those of previous tests using a module coated with PDD–TFE on the outside of the lumens. These results indicated that the major resistance to mass transfer in modules coated with PDD–TFE may be in the coating. Because PDD–TFE does have a relatively high resistance to mass transfer of VOCs, the need for a better polymeric coating is needed to improve process economics.

Table 5. PDD-Coated Membrane Results

Mass Transfer Coefficients					
PDD-Coated Membranes, Shell-Side (outside) Coating					
Compound Transferred	Air Stream			Solvent Stream	
	Concentration (ppm)	Flow (L/min)	Loading ^a (ppm/s)	Concentration (mg/L)	K ₀ (10 ⁻⁵ cm/s)
<i>m</i> -xylene	44	28	120	6.2	0.85
	50		130	6.2	0.91
	110		290	6.2	0.96

	250	60	1400	60	
	850	30	2400	80	
	650	30	1900	70	

Other activities aimed at acquiring a suitable coated module followed. Bend Research, Inc., supplied two prototype hollow-fiber modules for wet testing of the microporous Rayon fibers typically used in their scalable, high-flow, low-pressure-drop “box module” configuration. Results of the wet testing indicated that the pore size was too large for use in the system.

Chemica Technologies was contracted to coat a sample of the Celgard polypropylene fiber, and several small patches of coated material were received and tested as a VOC mass-transfer medium at North Carolina State University (NCSU). The results indicated satisfactory VOC transfer, but the coating partially delaminated from the substrate. Discussions continued with Chemica to assess their ability to improve coating adherence to internal lumen walls, but no satisfactory resolution was reached.

Celgard recommended a polyalkyl sulfone (PAS-16) and supplied some PAS-16 as well as a method for in situ fiber coating, the only option available for coating the Celgard module. With advice from Celgard and Anatrace, the PAS-16 manufacturer, a significant in-house effort with to coat the inside of the lumens with the PAS-16 polymer was begun. The coating attempts were based on Celgard's suggested method, which involved pumping a dilute polymer solution through the lumens while pulling vacuum on the shell side of the module. This was followed by rinsing and drying, followed by annealing the inside of the lumens with warm nitrogen (~60 °C). Variations in solvent, concentration of polymer, amounts of nonsolvent additives, operating conditions, annealing procedures, and drying and cleaning protocols were used. In initial attempts using tetrahydrofuran (THF) as a solvent (suggested by Celgard), the polymer did not dissolve completely, causing plugging in many of the lumens. Discussions with Anatrace and Celgard provided several new ideas, which included substituting toluene as the solvent, heating, blending, filtering, and centrifuging to improve solubility. After several trials, two of the four general approaches tried seemed to show promise toward achieving the desired results. These four approaches are summarized in Table 6.

Table 6. Fiber Coating Technique Development

TEST TYPE	SOLVENT	NON-SOLVENT	PAS-16 CONC. (%)	VACUUM (in. Hg)	CLEANING	DRYING	ADVANTAGES	DISADVANTAGES
1	THF	—	0.5 – 2	0 – 29.5	THF/Acetone mix to N ₂ -only purge	1–12 psi N ₂ 20 – 60 °C	Initial recommended solvent Compatible with module mat'l	Poor solvent for PAS Relatively expensive
2	Toluene	—	1 – 5	0 – 29.5	THF/Acetone mix to N ₂ -only purge	1–12 psi N ₂ 20 – 60 °C	Good PAS solvent Can be mixed with propanol to precipitate PAS	Drying more difficult More clogged lumens Unsatisfactory permeability results
3	Toluene	Propanol 40 – 45%	~1	0 – 19	Nitrogen	1–12 psi N ₂	Fewer clogged lumens Faster drying Predictable permeability results	
4	Toluene	Propanol added to shell side	~2	0	Nitrogen	1–12 psi N ₂	Precipitated PAS in pores	Difficult to control fluid permeation

To test for complete coating of the porous substrate, Anatrace suggested pressurizing one side of the membrane module with a mixture of nitrogen and carbon dioxide. Since carbon dioxide is seven times more permeable to PAS-16 than nitrogen, an analysis of the permeate could be used to determine whether coating was complete. Since that procedure is fairly difficult and time consuming to conduct, a simpler surrogate procedure was selected, at least for the initial tests as the coating procedure was being refined. This procedure is a permeation test in which nitrogen is admitted into the lumen side of the modules. The flow rate of nitrogen penetrating the lumen walls and escaping through the shell side was measured. A new module allows ~21 L/min flow at a selected pressure. Coating attempts conducted during this research exhibited flows ranging from 21 (uncoated) to less than 0.35 L/min. A module, flow tested at 0.35 L/min of nitrogen, was then tested and found to perform, in terms of mass transfer rate, much like the PDD–TFE-coated module. Since the PAS-16 coating is known to be more permeable to the VOCs tested than PDD–TFE, coating thickness was suspected to be excessive. Samples of lumens were cut out and viewed using a scanning electron microscope. The samples indicated a coating thickness of ~15 to 20 μm on the inside of the lumens; ~1 μm is the goal for coating thickness. Samples of a module that allowed nitrogen permeation at ~0.7 L/min showed a coating thickness of ~7 to 10 μm . From these preliminary tests, it is estimated that the proper permeability may be in the 1-to-1.5-L/min flow range to achieve a 1-to-2- μm -thick coating. It became evident that, although a reasonably successful technical exercise, this path would be time-consuming and would not validate a cost-effective approach.

Many discussions were held with commercial companies to determine the best approach to developing a separation/concentration module with a quality nonporous coating and a low-pressure drop. Proposals were solicited from Celgard, Bend Research, and Applied Membrane Technologies (AMT) for bench-scale modules and commitments to support the project with future larger-scale modules. Bend Research and AMT responded with proposals, and AMT was eventually selected as the manufacturer of choice.

3.2 Membranes Coated with Silicone Rubber

During searches for coated fiber modules, a company (AMT) was found that had developed modules for several water-stripping applications based on a coated fiber. They were asked to consider our application, and they offered a small, cylindrical module to be used for initial testing. The parallel-flow, stainless steel, cylindrical-membrane module was filled with fibers coated on the exterior with plasma-polymerized silicone rubber at a nominal thickness of 1 μm . Upon inspection prior to testing, a concern was raised because of the unknown effectiveness of the air-to-fiber contact area. AMT suggested that contact efficiency issues could be eliminated in a cross-flow module. Therefore, though the cylindrical parallel-flow design of the existing AMT module did not lend

itself to high efficiency, it was used in preliminary testing to gather data for the design of a cross-flow module.

Five 48-minute tests were conducted with air flowing through the shell side of the module: three were conducted using *m*-xylene as the pollutant, and two were conducted with MEK. Results are presented in Table 7. The airflow was typically 60 L/min, and VOC removal ranged from 56 to 83 percent with average overall mass transfer coefficients, K_o , of 4.4×10^{-6} to 5.0×10^{-5} cm/sec.

Table 7. Air-in-Shell Tests – Cylindrical Parallel-Flow AMT Module

Characteristic	<i>m</i> -xylene 1	<i>m</i> -xylene 1	<i>m</i> -xylene 1	MEK 1	MEK 2
Air flow (L/min)	60	60	60	28	60
Avg. inlet VOC air concentration (molar ppm)	65	190	185	186	1350
Average VOC removal (%)	56	77	70	83	78
Average mass transfer coefficient, K_o (cm/sec)	4.40×10^{-6}	8.30×10^{-6}	1.20×10^{-5}	2.10×10^{-5}	5.00×10^{-5}

In commercial operation, one may expect that contaminated air will flow through the shell side of a cylindrical design while the stripping fluid is pumped through the tube, or lumen side. The initial set of tests on the AMT cylindrical module was run in this manner. Because of the distribution and contact shortcomings encountered, AMT suggested that a second series of tests be conducted with the air flowing through the fibers. Therefore, a second set of tests was run with the air flowing through the fibers and octanol on the shell side. Twelve runs were conducted using *m*-xylene as the pollutant. These shorter (34-min) tests were conducted with airflow rates through the lumens ranging from 5.6 to 10.3 L/min at pressure drops from 11.5 to 20 inches H₂O (292 to 508 mm H₂O). Results are shown in Table 8. Each mass transfer rate reported in this table is an average of samples taken at four time points and has a variance of 0.17.

The K_o values (6.0×10^{-7} to 5.1×10^{-6} cm/sec) for this set of runs were consistently and significantly lower than for the air-in-shell results. As airflow decreases or as inlet concentrations increase, average VOC removal (overall) increases, but K_o , which is affected by other physical factors, may be impacted negatively. High removal efficiencies (93 and 97 percent) were achieved with octanol in the shell, and high mass transfer coefficients (2.1×10^{-5} and 5.0×10^{-5}) were achieved with air in the shell.

Table 8. Octanol-in-Shell Tests – Cylindrical Parallel-Flow AMT Module

Parameter	MX7	MX8	MX9	MX10	MX11	MX12	MX13	MX14	MX15	MX16	MX17	MX18
Air-side pressure drop [in. (mm) H ₂ O]	11.5 (292)	11.0 (279)	11.5 (292)	11.0 (279)	16.0 (406)	16.0 (406)	16.5 (419)	16.0 (406)	20.0 (508)	20.0 (508)	20.0 (508)	20.0 (508)
Air flow [L/min]	5.6	5.6	5.6	5.6	8.6	8.6	8.6	8.6	10.3	10.3	10.3	10.3
Avg inlet VOC air concentration [molar ppm]	68	84	261	684	92	125	457	499	76	105	274	697
Average VOC removal [%]	91	91	80	97	51	44	93	89	60	52	73	85
Average K _o [cm/s]	1.60 ×10 ⁻⁶	1.90 ×10 ⁻⁶	8.20 ×10 ⁻⁷	2.30 ×10 ⁻⁶	8.60 ×10 ⁻⁷	6.00 ×10 ⁻⁷	3.60 ×10 ⁻⁶	2.50 ×10 ⁻⁶	5.10 ×10 ⁻⁶	1.20 ×10 ⁻⁶	1.60 ×10 ⁻⁶	2.00 ×10 ⁻⁶

One problem encountered in all extraction experiments was swelling of the membrane material. Occasionally, this was accompanied by “sweating” of the octanol through the membrane. It will be necessary to evaluate alternate stripping fluids as a means to ameliorate this problem.

The information from this testing was used in the decision to develop a cross-flow module designed and manufactured specifically for this project by AMT (See Figure 4). This module contained roughly 2.3 m² of available membrane surface packaged in a module with air contact dimensions of roughly 3.5 × 10 × 1.0 inches (88.9 × 254 × 25.4 mm). Manufacturing methods required manufacturing in pairs, so the minimum two modules were procured.

Differences in design between the cross-flow and radial modules required a different potting material to seal the fibers into the end caps and plans were to use a urethane. This urethane material had not been previously used in applications with octanol, so limited tests were done to determine chemical compatibility. Initial results were only partially successful, showing softening of the urethane in longer periods of exposure. Using heat accelerated curing and longer setup times improved performance. These concerns and subsequent extended testing trials delayed the beginning of VOC tests. The urethane manufacturer concurrently investigated these issues, but they were unwilling to develop entirely new compounds and were unable to create small batches of existing materials to test. Few options were readily available.

Figure 4. AMT Cross-Flow Module – Overall Dimensions in Inches

After assembly of the modules, they were pressure-tested to prove compatibility with octanol. This was expected to be an easy test to pass because no compatibility issues surfaced with the radial module. However, during the test, elongation swelling of the polypropylene fibers was encountered in the new module. At this point, further testing was done with single fibers to prevent destroying the remaining module. It was also determined that, after removing the octanol and cleaning the module, the fibers returned to their original length. A number of tests were completed with single fibers exposed to octanol, and it was found that the stretching was limited to about 5 percent of total length. Three different manufacturers' fibers were tested; all produced similar results.

Disassembly and testing by AMT resulted in destroying one of the two modules that were built.

While a solution to the fiber stretching was being sought, the other module was received from AMT for inspection and airflow testing to determine how the cross-flow module performed in comparison to the goal of low pressure drop. The module was mounted in the custom steel transition sections, and a variable-speed blower and electrical controls were connected for the test. The results indicate that the module was able to pass 20 ft³/min of air at 0.62 inch H₂O pressure drop and 72 ft³/min at less than 4.0 inches H₂O pressure drop. Limitations of the test apparatus prevented using higher air flows. The goal for flow vs. pressure drop was 10 ft³/min at less than 20 in H₂O, so this design greatly exceeded this goal. With such a low pressure drop, multiple modules could be arrayed in series to increase VOC transfer performance, if needed. Inspection of the module and velocity profiles measured at the face of the fibers indicated that some bypass was created on the long sides where the fibers lay parallel to the polycarbonate housing. To address this problem, AMT proposed to create a seal along the two sides to limit the bypass. The fibers also exhibited some tendency to vibrate during the test, especially at the midpoint of the fiber bundle. AMT provided a modification to reduce or eliminate this vibration. At the end of the test, the module was returned to AMT for the modifications.

As indicated in Figure 5, the air pressure drop is negligible for this module, even at high flow rates. These results represent an order-of-magnitude improvement in pressure drop performance, relative to the cylindrical module containing identically coated fibers.

Figure 5 Pressure Drop for AMT Cross-Flow Module

The two approaches were available to address the fiber-swelling problem are (1) modify the housing in such a way that its length could be adjusted after the initial exposure to octanol, thereby re-tensioning the fibers, and (2) to use a stripping fluid other than octanol. The first method for fixing the stretching problem would involve redesigning the module to allow for post octanol length adjustment; this was abandoned due to complexity and an increased leakage risk. Alternate stripping fluids, including silicone oil and canola oil, were considered. Canola oil was seen as the most-economic alternative, but it lacked the chemical purity needed during analysis for extracted compounds. AMT then tested the fiber material with silicone oil in the same manner that had been used to measure the length changes after exposure to octanol. Single-fiber tests showed that fiber stretching was not evident after exposure to silicone oil, so a decision was reached to pursue switching to silicone oil. A change to silicone oil required repeating some of the initial octanol testing to verify partition coefficients at different temperatures for the compounds of interest. Potential toxicity to the bacteria also required investigation.

The AMT cross-flow module was returned for slight modifications and more tests using silicone oil in place of the octanol. The tests using silicone oil were successful; no swelling was seen, as had occurred in the case of octanol. AMT then returned the module after modifications were made, and a final decision was reached that further work on the separation contactor module would be done using silicone oil stripping fluid. An oil of viscosity slightly less than that of octanol (5 cs) was ordered and received. The single module was set up in a new apparatus for bench-scale testing using a simulated paint stream.

3.3 Experimental Structure

The bench scale S/C and biomembrane units were evaluated separately during the testing of the cross-flow separation contactor module. During the bench-scale testing, oil doped with the four target compounds was used in biomembrane effectiveness studies at N.C. State. During the final three months of the project, the used oil from the pilot-scale testing separation contactor system at ARCADIS was taken to N.C. State for biomembrane testing.

VOC mass transfer experiments require real-time sampling and analysis of VOC concentrations in inlet and outlet air and sampling of the stripping-fluid-reservoir VOC concentration for offline analysis. The VOC stream was created by a custom system configured as shown in Figure 6. The VOC-laden air stream is created by first injecting the four-component liquid mixture into a fitting that is heated by a small electric heater. This forces complete volatilization of the mixture before it is progressively diluted with filtered air until finally being force-mixed by a fan in the mixing box. During the mass transfer experiments, module inlet-stream VOC concentration was set via adjustments to the syringe pump delivery and airflow rates. Silicone oil flows were adjusted by a

Figure 6. Separation Module Bench-Scale Test Apparatus

pump-speed setting and were read on a rotameter. The system was allowed 5–10 minutes to stabilize before testing began. Once the experiment began, samples of the air at the inlet and outlet of the module (two air samples) were taken at approximately 2½-minute intervals and analyzed online by a gas chromatograph with a flame ionization detector (GC/FID). Oil samples were also withdrawn via syringe from an oil-sampling port located between the module outlet and the oil reservoir. These oil samples were taken at 5–10-minute intervals. The oil samples were then stored, headspace-free, at 3 °C for later analysis by GC. Analysis of air-side data resulted in a separation contactor removal efficiency, and oil-side analysis permitted a mass balance analysis of the system and determination of the oil condition from test to test.

3.3.1 MBT Bench-Scale Separation Contactor

A schematic of the bench-scale system separation contactor is shown in Figure 6 and a process flow schematic is presented as Figure 7.

Figure 7. Process Schematic of Separation Module Bench-Scale Apparatus

3.3.2 Pilot Testing

A schematic of the complete MBT system appears as Figure 1 in Section 1.1.1. A process such as a paint booth produces a dilute stream of VOCs in air. After particles are filtered from the stream, it enters an S/C unit, which employs bundles of microporous hydrophobic fibers with the VOC-laden air and stripping fluid flowing across and through the fibers, respectively. The VOCs are transferred from the exhaust gases into the stripping fluid medium. The stripped air that leaves this unit is taken to an exhaust stack. After the circulating silicone stripping fluid leaves the S/C unit, it is delivered to a biomembrane unit is stored in an intermediate storage vessel. In the biomembrane unit, the stripping fluid is circulated past one side of another microporous membrane module that has a film of VOC-degrading bacteria on the opposite side of the membrane. VOCs diffuse through the membrane pores and are selectively and completely metabolized by the bacteria. The stripped solvent is then collected in a storage vessel and recycled through the S/C unit. Outputs from the overall MBT system are clean air, carbon dioxide, and a mixture of water and nonhazardous cell mass.

A diagram of the pilot-scale system is shown in Figure 8. The pilot-scale system differed from the bench-scale description in a number of details, including that the system was much larger and that the stream was created from spraying actual coatings from a paint spray gun pointed at a target in a small tabletop paint booth. The coating used for these experiments were acquired from an Air Force refinishing facility, and its components were determined from Material Safety Data Sheets (MSDS). However, paints are not composed of pure compounds, and industrial versions of listed compounds (e.g., MEK) are typically a mix of many compounds. Also, components below 1 percent are not required to be listed on an MSDS. Therefore, the capture efficiency was measured by using a total hydrocarbon analyzer on the upstream and downstream air streams rather than by speciation with a GC/FID. For these same reasons, a hydrocarbon analyzer is the instrument typically used to measure paint booth control equipment destruction efficiency in commercial operations. Based on previous work at NCSU, it was assumed that the separation contactor module could display selective removal behavior. To look for module compound preferences, samples were also taken for analysis with a GC/mass spectrometer (MS). These samples were taken on charcoal sorbent tubes at input and output locations adjacent to the sampling ports for the total hydrocarbon analyzer and were analyzed against a list of typical paint compounds, including those listed in Table 9. The oil analysis was done the same as for the bench scale. Testing followed the matrix outlined in Table 10.

4.0 Results/Data

The following sections present the results of the experiments performed during this study. Pertinent data from bench- and pilot-scale tests can be found in Appendices B and C, respectively.

4.1 Separation Module Tests

Separation module tests, described below, was performed in a number of bench- and pilot-scale modules.

4.1.1 Bench-Scale Tests

Eighteen successful tests, summarized in Table 11, were completed using a variety of air flow rates, VOC loadings, and oil conditions. Average removal efficiencies varied from 4.4 to 73.7 percent, and peak removal rates exceeded 79 percent twice for *ortho*-xylene. A question was raised about the performance of the GC after test nine, so the steps were expanded to include pre and post test calibrations. Preparation of calibration standards had also been inconsistent prior to this test, so alternate methods were found to improve consistency. For this reason, there is more confidence in the results from tests 12 and higher, but tests did just as well with 17 percent of the loading. Nevertheless, the results show important trends and general information. Higher loadings, such as in Test 2, improved inlet/outlet removal efficiency. Typical paint booth operations will have emissions in the range of 200 to 350 ppm, so most of the tests were run within that range. Higher air flow rates were used in a few tests to determine if increased turbulence improved performance, but it appeared that any such performance increase was negated by shortened contact time, resulting in lower removal efficiencies. Two modules arranged in series improved performance over a single module. Higher oil flow resulted in higher removal rates, but leaks resulted if this flow were set too high, indicating that materials and the module structure required improvements. Although overall removal efficiencies for individual compounds were as high as 79 percent, VOC removal rates were highly variable; MEK removal was often well below acceptable values, especially considering its prevalence in military coatings. Even though MEK removal was often at or close to zero, the other three compounds were consistently removed and were relatively comparable from test to test.

The first module received from AMT was the one not damaged during the initial testing. After a few trial runs with the lab apparatus, the module was tested for VOC removal efficiency. As a starting point, pressures and flows were chosen based on previous bench-scale investigations at NCSU using the uncoated fibers of the Celgard module. Oil flow was set at 1.0 L/min and air flow at 2.0 ft³/min. It became apparent after two tests that the module was leaking oil, and swelling of an internal silicone rubber bridge was creating packs and voids in the fibers. This substantially reduced the

contact efficiency and performance was deteriorating, so testing was stopped after Test 5. An inspection of the module was unable to locate the exact source of the leak, but previous experience had shown the corners where the module sections were assembled to be suspect. A problem with the urethane material was assumed to be the culprit. Two modules received later were constructed similar to the first two, but an alternate potting material was used so that testing could continue while the urethane problems were investigated further. Tests with these modules were started with a lower oil pressure and more conservative flow rates (0.2 L/min) to prevent leakage failures. Removal efficiencies were lower during the next tests, most likely because of the lower driving forces from the reduction of oil pressure and flow. A number of modifications were made to the return piping on the apparatus to reduce back pressure in hopes of increasing oil flow without raising the static pressure. This was successful in bringing flow up to 0.4 L/min with a back pressure of about 5.0 psi. Results showed an obvious increase in removal efficiency, although still lower than the target of 80 percent. The two modules were then arranged in parallel on the oil side and in series on the air side to double the contact time without risking higher oil pressures. The efficiency again increased, but not as dramatically as had been achieved with higher oil flow rates, so the next step was to increase the oil flow and pressure. Again, plumbing modifications were made to reduce back pressure, and flow was increased to 1.0 L/min with an increase in pressure to 12.5 psi. Although removal efficiency increased, it quickly became apparent that both modules were again leaking oil. Based on these trials, AMT proposed a number of design modifications to be used in the pilot-scale version to prevent the leakage problems of the corners and joints.

4.1.2 Pilot-Scale Tests

Pilot-scale testing produced several tough challenges that reduced the number of successful tests. Initial runs were hampered by inconsistent spray gun paint application, although the apparatus was designed to maintain a constant trigger position. In addition, only the last five tests were run with both air-side analytical systems. Upon data review, the comparability of these two analytical methods and its implications are important enough to focus primarily on these results, shown in Table 12. The overall removal rate is shown by averaging the GC/MS results for the eight listed compounds and by the average removal reported by the total hydrocarbon analyzer. For all five tests, both methods passed pre-and post-analysis calibration checks. However, agreement was achieved only for Tests 1 and 3, with 7.4 and 16.9 percent differences, respectively. Comparability for Test 5 was lower at 35.6 percent difference, and Tests 2 and 4 show gross differences. Similar trends were seen for the bench-scale module in that MEK shows much lower results compared to the other compounds, and removal generally improves with higher oil flow and lower air flow.

To understand the removal results requires a short review of the methods used. During bench-scale testing the air-side analytical method (GC/FID) agreed closely with the oil-side analysis method in

Table 12. Summary of Pilot-Scale VOC Tests

total mass balance. This was largely due to using four pure compounds to create the pollutant stream, and each method could differentiate and quantify the known four compounds. The change to pilot-scale brought the use of real paint to simulate a paint-booth exhaust. It was known beforehand that even compounds listed on the MSDS, such as MEK and xylene, would be impure compounds that would have significant variations in constituents. For this reason, the air-side analysis was changed to a total hydrocarbon analyzer because it would be capable of analyzing all known and unknown VOCs. Because no better alternative existed, the oil-side analysis was unchanged and analyzed for only the same four constituents identified during the bench-scale testing. An additional analysis was added for the air side with the knowledge that the module could turn out to be selective in its removal rate; additional samples were taken parallel with the total hydrocarbon analyzer to be analyzed by EPA Method 25. These carbon tube samples were extracted and analyzed on a GC that is normally used for identifying unknown compounds in coatings formulations. A sample run identified eight compounds on the standard search list.

Pilot-scale test results were variable and, at times, difficult to understand. Initial test results using the total hydrocarbon analyzer showed inlet and outlet results varying from 20 to 65 percent removal. Oil analysis, however, almost never agreed with those removal rates, and during later tests, when charcoal tubes were analyzed by GC/MS, averaged removal rates based on the eight constituents were always reported higher than those with the other two methods. To understand this, it is important to remember that each method was different and comparability was not a given. The total hydrocarbon analyzer measures total carbon atoms, and the relationship between its readout in parts per million and the other methods requires the use of a multiplier to account for the more-complex molecular structure of organic compounds. Regardless, with any reasonable factor (e.g., 4.0 for typical paint compounds), the data from GC/MS barely exceed 1 percent of the reading produced by the total hydrocarbon analyzer. This implies that the eight compounds that were identified by GC/MS represented only 1 percent of the total constituent VOC content of the paint, and while the module was relatively efficient at removing some compounds, especially those identified by the GC/MS, it was unable to remove other compounds, especially after the oil had been used. The total hydrocarbon analyzer reported an overall VOC removal rate that was comparable to the rate reported by GC/MS at times and not comparable at other times.

More problematic was that the oil analysis data rarely reflected the air side removal. In some cases, the oil showed no removal, while the air side showed removal of 20 percent or more. One contributing factor is that the oil analytical procedure was developed during the bench-scale studies, and calibrations were based on removal of four, well characterized, pure compounds rather than the eight identified in the GC/MS samples, or the many unknown compounds contributing to the total hydrocarbon analyzer data. However, with even the four known compounds, the GC/MS data did not always agree with the oil data. A possible explanation is that much of the stripped VOCs did not

pass through the fiber boundary but, rather, was adsorbed and temporarily held both on the wetted outer surface of the fibers and by the static oil that had formed a puddle inside the apparatus during the tests. Contributing to this theory is a daily operational aspect. Each time a test was completed, the air fan was left running to prevent migration of the paint vapors to office areas adjoining the laboratory. During this time, the oil outside the fibers that had adsorbed VOCs was thus desorbed, and this cleaned oil was again the dominant remover during the next test.

To treat the needed 500 ft³/min, 20 modules were ordered with the latest in design specifications of the bench-scale module: 2.3 m² area and 3.5 × 10 × 1.5 inches (89 × 254 × 38 mm). Although scaling up by using many small modules was not an ideal approach, project time requirements for delivery required using existing production methods, and this was the largest size that could be made with existing production equipment. To reduce bypass around the side, a shelf area was added to overlap the fibers, and the silicone rubber bridge that became distorted on the first bench-scale version was dropped. One advantage of the small modules was that, to suit various test scenarios, they could be arranged in a range of patterns such as multiple banks of module for increased contact time or parallel arrangements for greater air flow rates. The rest of the apparatus (module mounting frames, ducting, transitions, and oil piping) was designed with this in mind, and to reduce assembly time, the transitions and mounting frames were constructed while the modules were in production.

After the 20 modules were delivered, a number of tests were done to determine their basic integrity. Although AMT tested the modules under pressure with air, no tests had been done with silicone oil. Therefore, each module was to be unpackaged, visually inspected, and then tested under 5 psi oil pressure. Based on visual inspection, several of the modules exhibited question-able potting material with bubbles and extrusions. The bubbles were due to the urethane curing at humidity that was not ideal. Two with obvious porosity problems were chosen for pressure testing, and each leaked almost immediately upon start up. This was seen as serious enough to warrant stopping further tests while AMT addressed the problem. After these were sent back, AMT determined that one was damaged in shipment and could be repaired. To conserve the short time remaining in the project, a decision was reached to test some of the remaining modules. The apparatus was easily able to test 10 modules arranged in two series-arranged banks. Therefore, they were assembled into a reduced-size, pilot-scale apparatus so testing could begin. This required a reduction in airflow from the planned 500 cfm. The maximum treated stream was 200 cfm.

Meanwhile, AMT was unable to locate the leak in the second returned module. The leak that had been seen during receiving tests was the result of a slow, but continuous, sweating of oil through the pores of the fibers. This suggested a difference between AMT's tests and the receiving tests; the receiving tests had used silicone oil with a viscosity similar to octanol, or about 5 cs, whereas AMT's tests were done with the more commonly available 50-cs oil. Further study revealed that the

thinner silicone oil was acting more solvent-like; it was seeping through the pores of the fibers, both wetting the outside of the fibers and accumulating, over time, in a puddle at the bottom of the module. Based on this information, AMT advised that further tests should be limited in pressure and oil flow rate.

After a number of tests with the 10-module arrangement, the apparatus was disassembled for a visual inspection, and it was apparent that wetting the fibers had created a problem that had previously gone unnoticed. The fibers were again distorted much like had occurred during the bench-scale testing. It was then determined that the distortion was not due just to swelling the silicone rubber bridge that had been deleted from the design but was also due to individual fibers swelling much as had occurred in the octanol compatibility tests. The thinner, 5.0 cs oil had acted on the fibers much like an aggressive solvent, and the stretching was creating voids and packed areas. Therefore, the modules had an unknown, but certainly not optimal, contact efficiency. At this time, AMT recommended that we use the remaining 10 modules in another test using the thicker, 50 cs oil. Their reasoning was that the thicker oil would be unlikely to seep through the fibers. After assembling the remaining 10 modules, a shakedown test was started. To attain the same flow rate that was used in previous tests required a much higher pressure (about 30 psig) setting, and one or more modules ruptured, causing a catastrophic loss of oil, and the testing was stopped. In retrospect, while thicker oil would be less likely to seep through the fiber, its viscosity requires much higher pressure for any given flow rate. To prevent failure of the urethane potting material would have required a much lower flow rate, and with lower flow rates, the driving forces would be reduced, so any advantages may have been lost. Contaminated stripper fluid from the pilot plant was transferred to the NCSU laboratory for bio-treatment.

4.2 Biological Treatment System

The experiments related to the biological treatment system can be organized into four major categories of suspended cell experiments performed in shake flasks, biofilm experiments performed in flat-sheet membrane units, biofilm experiments performed in hollow-fiber membrane units, and experiments involving hollow-fiber units in series with a stirred tank reactor. These categories represent qualitatively different objectives.

- Shake flask (suspended-cell) experiments determine organism and mixed-culture characteristics,
- Flat-sheet biofilm experiments determine the basic behavior of pure- and mixed-culture biofilms,
- Hollow-fiber-module experiments determine the robustness of the degradative activity and evaluate biofouling control schemes, and
- Experiments involving the hollow-fiber module operated in series with a suspended-cell

reactor demonstrate the capability to simultaneously degrade aliphatic and aromatic VOCs.

Characterization of the performance of the bacterial consortium on mixed VOCs is confounded by three facts: (1) growth and degradative behaviors of a mixed culture cannot be expected to be the sum of the behaviors for each organism in the culture grown separately; (2) immobilized-cell (biofilm) growth kinetics often deviate significantly from suspension-culture (shake-flask) growth kinetics; and (3) growth of a single organism on a mixture of compounds is not easily related to growth on the individual compounds.

The complex interactions between species and compounds must be identified and quantified before one can effectively design and operate a biotreatment module. To adequately describe the behavior of this system, a series of suspended-cell-growth studies and membrane-supported-biofilm-reactor experiments were completed. Complete data sets for each experiment can be found in Appendix B.

4.2.1 Suspended-Cell Experiments

A significant number of growth studies were performed during the course of this research, many in response to the degradative behavior exhibited by the mixed-biofilm reactor system. The first set of experiments to be described pertain to the need to identify degraders for compounds found in MilSpec paints; specifically *m*-xylene, *p*-xylene, ethylbenzene, butyl acetate, butanol, MEK and acetone.

4.2.1.1 Screening Studies

Original screening studies were performed to identify organisms capable of degrading *m*-xylene, and two organisms were ultimately established with those capabilities, respectively designated MX-1 and X1. Subsequent screening studies were undertaken to establish degradation of *p*-xylene, ethylbenzene, butanol, butyl acetate, and acetone.

4.2.1.2. Xylene Degraders

The first of these studies involved the screening of MX and X1 for growth on *p*-xylene and ethylbenzene. This was done to select one of the two different strains for further studies.

Methods: Cultures were grown under sterile conditions in 250-mL flasks incubated at 30 °C in a shaker (250 rpm). The flasks contained 50 mL of L-salts medium; individual VOCs were added as liquid in quantities of 5–7.5 µL. The flasks were covered with foil and sealed with Parafilm before incubation. Optical density of the culture at 600 nm was monitored for up to 72 hours to detect growth. The initial concentrations of *p*-xylene and ethylbenzene were 150 ppm and 100 ppm, respectively.

Results: Both organisms were able to grow on *p*-xylene, but only X1 grew on ethylbenzene. Based on these results, X-1 was chosen for the staged biotreatment experiment.

4.2.1.3 Aliphatic Degraders

Two organisms that had been isolated previously, designated M1 and AOC-1, were screened for growth on butanol, butyl acetate, MEK, and acetone. This was done to select the better aliphatic-compound degrader of the two strains for the staged biotreatment study.

Methods: Cultures were grown under sterile conditions in 250-mL flasks incubated at 30 °C in a shaker (250 rpm). The flasks contained 50 mL of L-salts medium; individual VOCs were added as liquid in quantities of 5–7.5 µL. The flasks were covered with foil and sealed with Parafilm before incubation. Optical density of the culture at 600 nm was monitored for up to 72 hours to detect growth. Initial concentrations of all substrates were 150 ppm.

Results:

Organism	MEK	Acetone	Butanol	Butyl Acetate
M1	+	+	+	+
AOC-1	(-)	+	+	+

M1 grew on all four substances. AOC-1 grew on acetone, butanol, and butyl acetate; but growth on MEK was very uncertain. Therefore M1 was chosen for the staged biotreatment experiment.

4.2.1.4 Growth Studies

Many growth studies were carried out in conjunction with screening studies to quantify growth rates and extents of VOC degradation. These growth studies involved the organisms MX, X1, and M1. Table 13 summarizes the experiments performed over the course of the project. Only the experiments that have not been described in previous reports or publications will be commented on directly; the results of all the experiments can be found in the appendices. Although each experiment involved specific organisms and substrates, a general methodology was employed for culture growth and characterization.

Culture growth: Growth flasks were prepared under sterile conditions in screw-top flasks. L-salts were added to the flask, and the headspace was filled with oxygen. The substrate was added, and inoculation was effected by adding a sufficient amount of an overnight culture to a total liquid volume of 150 mL. The flask was sealed with an open-top closure with a PTFE-coated septum, and a needle pierced through the septum connected to a Teflon valve. A control flask was prepared in a similar way but without inoculation. Liquid was withdrawn by use of a glass syringe for optical

Table 13. Suspension-Culture Experiments

Experiment No.	Organisms	Substrates	Rationale
GS1	X1	<i>m</i> -Xylene	Strain characterization

GS16	M1	MEK, butyl acetate	Metabolic regulation

density (OD) and VOC measurements. During the sampling, oxygen was added to the flasks to compensate for the volume withdrawn. The control flask was treated in the same way, but the samples for OD were discarded.

General analytical procedure: The sample withdrawn for VOC analysis (1 mL) was transferred into a 2-mL vial containing 1 drop of acetic acid to acidify the sample. Extraction of the VOCs was carried out by addition of pentane (0.1–0.2g) containing heptane as internal standard. The sample was shaken vigorously for 2 minutes and stored upside down at 5 °C. Analysis was performed with a Hewlett–Packard 5890 gas chromatograph (GC) equipped with a J&W Scientific capillary column (DB-624) and a FID detector. A 1-μL portion of the pentane phase was injected into the GC, and the response was compared to the response from standards prepared in pentane.

4.2.1.5 MX and X1 Growth on *p*-Xylene (GS 11, 12)

The objective of these experiments was to study the growth and degradation of *p*-xylene by the *m*-xylene-degraders in order to choose the best organism for xylene degradation in the staged biotreatment unit. The substrate (*p*-xylene) was added so that initial concentrations varied from 100–150 ppm.

Results:

Organism	Growth Rate (h ⁻¹)
MX	0.29
X1	0.49

The inoculum was grown on *m*-xylene, so not surprisingly both organisms exhibited a long lag phase (20–30 hours). The growth rates indicate that X1 degrades *p*-xylene more rapidly than does MX. Although suspension culture behavior is not completely indicative of the behavior of organisms when attached to a surface, X1 was selected for further evaluation.

4.2.1.6 Effect of Ethylbenzene on Growth of X1 on *m*-Xylene (GS13)

The objective of this experiment was to determine whether ethylbenzene has a positive or negative effect on the rate of degradation of *m*-xylene by X1. This would indicate whether the pathways involved in the degradation of these two compounds were synergistic, antagonistic, or non-interactive.

Methods: Growth flasks were prepared as described above. The initial concentration of *m*-xylene was 150 ppm in all flasks. Initial concentrations of ethylbenzene were varied: 0 ppm, 50 ppm, 100 ppm, and 150 ppm. The flasks were closed as described above. Optical densities were followed for 26 hours.

Results: Ethylbenzene appeared to have very little effect on the growth rate. It seems that the initial lag phase was shorter in the presence of ethylbenzene, indicating that the presence of ethylbenzene might facilitate *m*-xylene degradation. Another possibility is that ethylbenzene was degraded as well. However, no VOC analysis was undertaken.

The presence of ethylbenzene in high concentrations (150 ppm) did affect the apparent growth yield obtained after 26 hours. For an initial concentration of ethylbenzene of 150 ppm, the final optical density was 0.17 compared to 0.24–0.26 for cultures exposed to lower concentrations of ethylbenzene. The growth had reached a stationary growth phase in all the flasks, which was confirmed by a sample point after 32.5 hours. The lower OD level for the high concentration of ethylbenzene indicated that the growth of X1 on *m*-xylene was inhibited rather than ethylbenzene was degraded itself. For further study of the effect from ethylbenzene, VOC analysis should be done to determine if ethylbenzene is being degraded. The table below shows the growth rates calculated for each concentration of ethylbenzene, and the optical densities of each culture after 26 hours.

Concentration of Ethylbenzene (ppm)	Growth Rate (h^{-1})	Period for Exponential Growth (h)	OD after 26 hours
0	0.23	11 – 19	0.24
50	0.20	7 – 16.5	0.26
100	0.24	7 – 16.5	0.24
150	0.22	4 – 16.5	0.17

4.2.1.7 Growth of X1 on *m*-Xylene and *p*-Xylene (GS14)

The objective of this experiment was to study the growth and degradation of mixtures of *m*- and *p*-xylene by X1. Again, the concern was that there might be negative interactions between the two degradative pathways or intermediates generated therein.

Methods: Growth flasks were prepared as described above; *m*-Xylene and *p*-xylene were added to a concentration of 75 ppm each.

Analytical procedure: It was not possible to separate *m*-xylene from *p*-xylene, so a total concentration of the two xylenes was calculated.

Results: The growth curve indicated that the two substrates were degraded concurrently. The growth took place within 10 hours, and no lag phase was observed. After 9 hours, *m*-xylene and *p*-xylene could not be detected in the liquid. The growth rate obtained in this study is compared to growth rates determined in previous studies of X1 growing on *m*-xylene and *p*-xylene as single substrates. Results show that the growth rate obtained in the presence of both substrates is lower than the one obtained when only *m*-xylene is present, but higher compared to the growth rate obtained for *p*-xylene.

Substrate	Growth Rate (h^{-1})
<i>m</i> -Xylene	0.78
<i>p</i> -Xylene	0.49
<i>m</i> -Xylene + <i>p</i> -xylene	0.58

4.2.1.8 M1 Growth on Butyl Acetate and a 50:50 Mixture of Butyl Acetate and MEK (GS 15, 19)

The objective of these experiments was to study the effect of butyl acetate on the rate of MEK degradation and of growth of M1 on MEK.

Methods: For the study with butyl acetate, the concentration of substrate in the flask was 150 ppm, whereas concentrations of butyl acetate and MEK were 75 ppm each for the mixed-substrate study.

Results: The growth curve indicated that butyl acetate and MEK were degraded concurrently. An effect from the presence of MEK was seen on the growth rate for butyl acetate; the growth rate obtained for the mixture of butyl acetate and MEK was lower than that obtained for M1 growing on butyl acetate alone.

Substrate	Growth Rate (h ⁻¹)
MEK	0.5
Butyl Acetate	0.70
MEK + Butyl Acetate	0.57

4.2.2 Flat-Sheet Biofilm Experiments

Experiments were performed utilizing a small contactor using a flat, square section of porous polypropylene substrate. The basic configuration employed in these studies is shown in Figure 9.

Figure 9. Flat-Sheet Contactor Schematic

The system was operated under countercurrent flow with a flow rate significantly smaller than the recycle flow rate, resulting in well mixed fluid in the reservoirs and on each side of the membrane within the contactor. This configuration was adopted because it allowed relatively rapid establishment of films and determination of degradative activity and because the film could be sampled directly for characterization (thickness, composition).

Initiation of all of these experiments involved aqueous phases on both sides of the membrane, with the substrate being provided through the membrane in all cases. Subsequent to establishment of a viable, active biofilm, the feed fluid either remained aqueous or was switched to an oleophilic fluid (octanol or silicon oil, for example).

Flat sheet biofilm experiments were conducted according to the matrix in Table 14.

Table 14. Flat-Sheet Biofilm Experiments

Experiment No.	Organism(s)	Substrate(s)	Comments
FS1	M1	MEK, toluene	aq/aq
FS2	M1	MEK	aq/octanol
FS3	M1, X1	MEK, toluene	aq/aq
FS4	M1, X1	MEK, toluene, <i>m</i> - xylene	aq/aq
FS5	M1, X1	MEK, toluene	aq/octanol
FS6	X1	<i>p</i> -Xylene	aq/aq
FS7	X1	<i>m</i> - Xylene	aq/aq
FS8	X1	<i>m</i> - Xylene, <i>p</i> -xylene	aq/aq
FS9	X1	<i>m</i> - Xylene, <i>p</i> -xylene	aq/silicone oil

General experimental procedures: During experiments to determine the degradative capacity of the biofilm developed on the membrane, a 1-L flask containing 800 mL of oxygenated L-salts (reservoir) replaced the chemostat (CSTR), and a 1-L flask with 800 mL feed solution replaced the feed bottle. Both flasks were stirred, and flow rates were as given above. For analyses of VOC concentration, 1.0-mL samples were withdrawn hourly. VOC concentrations in the reservoir and feed bottle were followed for at least 5 hours.

General analytical procedures: The liquid samples were transferred to a 2-mL vial containing 1 drop of acetic acid for preservation. VOC extraction was carried out by adding pentane (0.1– 0.2g) containing heptane as an internal standard. The sample was shaken vigorously for 2 minutes and stored upside down at 5 °C. Analysis was performed with a Hewlett–Packard 5890 GC equipped with a J&W Scientific capillary column (DB-624) and a FID. A 1-μL portion of the pentane phase was injected into the GC, and the response was compared to the response from standards prepared

in pentane. A total xylene concentration was calculated for experiments involving both *p*-xylene and *m*-xylene because it was not possible to separate the two xylenes in the GC analysis.

4.2.2.1 Growth of X1 on *m*-Xylene and *p*-Xylene (FS 6, 7, 8)

The objective of these experiments was to study the degradation capacity and biofilm characteristics of a xylene-degrading biofilm. Degradation of *m*-xylene and *p*-xylene supplied as single substrates and as part of a mixture were investigated.

Experimental configuration: Two flat-sheet contactors connected in series were run co-currently with aqueous solution on both side of the membrane. The biofilm side was connected to a CSTR and the opposite side (feed-side) was connected to a feed bottle saturated with the VOC. A slow airflow was passed through a pure solution of the VOC (*m*-xylene or *p*-xylene), and the exhaust air was fed to the bottom of the feed bottle, obtaining a saturated solution. The feed-bottle contained 5 liters of distilled water. Operational data were as follows:

Parameter	Value
Volume of CSTR	1-L vessel with 500 mL culture
Average flow of L-Salts to CSTR	30 mL/h
Ph in CSTR	7.0
Temperature in CSTR	30 °C
Flow on feed side	7.7 L/h
Flow on biofilm side	34 L/h

The CSTR was inoculated with X1. When exponential growth was obtained in the CSTR, the contactors were inoculated by passing the suspension over the membrane on the biofilm side.

Results: Experiments were carried out for two levels of *p*-xylene and *m*-xylene. The feed was prepared from the saturated solution, which made the concentration difficult to control. For the last two experiments reported below (A, B), the feed solution was made by adding the pure VOCs to distilled water that had been oxygenated for 10 minutes. An overview of the experiments is shown.

After the experiments with *p*-xylene, the biofilm was harvested, and the system was inoculated again. A very thin biofilm with black and gray spots was observed on the membranes. The second biofilm was grown for 38 days. After 38 days, the biofilm appeared yellow and was filling out the space between the support material and the membrane to the thickness allowed by the gasket.

Substrate	Level	Age of Biofilm (days)
<i>p</i> -Xylene	High	5
	Low	7
<i>m</i> -Xylene	High	5
	Low (150 ppm)	10 ^A
<i>p</i> -Xylene + <i>m</i> -Xylene	100 ppm of each	25 ^B

Results: All experiments exhibited very low VOC concentrations in the film-side reservoir. The concentrations were below 1 ppm except for the first experiment, for which a high concentration (26 ppm) was observed for the very first point and an increase from 0.1 ppm to 4 ppm was observed during the 10-hour run. Because of the insignificant concentrations in the film-side reservoir, the removal of VOC from the feed may be considered as the amount degraded in the biofilm.

For the young biofilms (5–7 days), the average removals of *p*-xylene and *m*-xylene from the feed bottle were in the range 4–11 ppm/h. For the 10-day-old biofilm, the average removal of *m*-xylene was 20 ppm/h. However, the removal appeared to take place only during the first 4–7 hours of exposure to the substrate. After 4 hours, the concentration in the feed bottle established a constant level and no further degradation was seen. This could be due to oxygen limitation in the system, as no oxygen was supplied during the experiment. For the 10-day-old biofilm, the feed solution was oxygenated prior to the experiment, which may explain the higher removal. This could also be due to growth of the biofilm and, hence, an increase in active biomass. For the same experiment, the reservoir was replaced by a new oxygenated reservoir after 21 hours. After the replacement, additional substrate removal was observed, which may confirm that the *m*-xylene degradation was oxygen-limited.

When *p*-xylene and *m*-xylene were supplied as a mixture, the biofilm was 25 days old, and an average removal of 60 ppm/h was observed for the first 2.5 hours. The feed solution was also oxygenated prior to this experiment, making higher removal possible. However, the removal obtained in this study (150 ppm) compared to the removal obtained in the study with the 10-day-old biofilm (80 ppm) should be equal if the amount of oxygen was the critical limitation, since the same amount of oxygen was supplied in the two experiments. The discrepancy between the two results may still be oxygen limitation, but a limitation inside the biofilm rather than in the aqueous phases.

4.2.2.2 Growth of X1 on *m*-Xylene and *p*-Xylene (FS 9)

The objective of these experiments was to determine the ability of the biofilm to extract substrate from an oleophilic feed fluid.

Experimental configuration: Two flat-sheet contactors were connected in series. After establishment of the biofilm (1–2 weeks), the activity of each contactor unit was determined separately. In each case, silicon oil was fed to the feed side, and L-salts medium was fed to the biofilm side. The oil and the L-salts were run counter-current in closed loops. The capacity of the contactor unit was determined by following the concentration of the substrate in both reservoirs after spiking the oil with VOC. After determination of the capacity, the biofilm was harvested, and samples for biofilm thickness (wet weight), cell count, and protein content were collected.

Results: Removal of *m*-xylene and *p*-xylene from the silicone oil was not detectable during the 25-hour- long experiment.

Contactor	Film Age (days)	Biofilm Thickness (μm)	Protein Content ($\mu\text{g}/\text{cm}^2$)	Cell Count (cells/cm^2)
1	12	14	4.7	24×10^6
2	19	95	—	86×10^6

4.2.3 Hollow-Fiber Membrane Experiments

A series of experiments using hollow-fiber modules was performed to establish the efficacy of the proposed biotreatment module for enhanced VOC removal from the octanol. The liquid/liquid stripping efficiency of MEK (octanol to water) was determined for the biotreatment module both with and without a biofilm present. Three aqueous (absorbent) flow rates were examined, with a constant 5000-ppm MEK concentration in octanol and an octanol flow rate of 290 mL/min. Samples were taken in duplicate. Results shown in Table 15 (comparing the 301-mL/min flow, abiotic vs. biofilm) indicate that the presence of a live biofilm enhanced MEK removal by approximately 43 percent.

Table 15. Biomembrane Mass Transfer

Experiment Type	Abiotic			Biofilm
Aqueous Phase	filtered tap water			L-salts ^a
Q _{aqueous} (mL/min)	116	301	598	301
Q _{octanol} (mL/min)	290			
MEK in Octanol (ppm)	5000			
Mass Transfer Rate (g/m ² h)	1.80	2.07	4.45	2.97

^a pH-balanced trace-nutrient source for microbiological organisms

4.2.4 Staged Biotreatment of VOC Mixtures in Lab-Scale Reactor

A membrane bioreactor for treatment of a broad range of compounds found in paints for aircraft was set up. Different levels of water solubility among the compounds suggested a staged bioreactor comprising a membrane contactor (Liqui-Cel) and a chemostat (CSTR). VOCs were supplied to the Liqui-Cel in silicone oil. The Liqui-Cel served as the reactor for removal of compounds with low water solubility, whereas compounds with high water solubility are more likely to be removed in the CSTR. The objective was to study the performance of the staged bioreactor system and to study the degradative capacity for mixtures of VOCs with different water solubilities in the bioreactor system inoculated with two organisms. A limited number of VOCs were chosen, and the removal of these compounds was monitored. VOC-contaminated oil obtained during air treatment was treated as well.

Experimental configuration: A Celgard Liqui-Cel unit with polypropylene fibers was used as the membrane contactor. The volume of the shell side was 0.4 L and of the lumen side was 0.15 L. The oil passed through the lumen side at a flow rate of 54 mL/min. (3.2 L/h). A CSTR with a liquid volume of 4 L was connected to the shell side, and the bacterial suspension was passed through the shell side in a counter-current mode. The flow rate of the aqueous phase was 400 mL/min (24 L/h). Aerated L-salt medium was supplied to the CSTR at 100 mL/h. The temperature was set at 30 °C, and pH was adjusted to 7.0. The supply of L-salt medium to the CSTR was turned off during the experiment, and the outlet and the air vent from the reactor closed. Oil samples were withdrawn from the oil reservoir, and aqueous samples were taken at the inlet and outlet from the Liqui-Cel. M1 and X1 were cultivated in a 1-L chemostat, and when exponential growth was obtained, the Liqui-Cel was inoculated by passing the suspension through the shell side. The attached CSTR was inoculated with M1, and after reaching exponential growth, the reactor was supplied with L-salt medium containing MEK until a biofilm was established. The systems were combined, and oil containing both MEK and *m*-xylene served as the substrate source.

Analytical procedure: All oil samples and aqueous samples containing both MEK and butyl acetate or paint components were analyzed by ARCADIS. GC analysis was performed on the aqueous samples for determination of the aromatics, and high performance liquid chromatography (HPLC) analysis was done to determine aqueous MEK concentrations. Samples for aromatics were transferred to 2-mL vials containing 1 drop of acetic acid for preservation. Extraction of VOCs was carried out by addition of pentane (0.1–0.2g) containing heptane as internal standard. The samples were shaken vigorously for 2 minutes and stored upside down at 5 °C. Analysis was performed with a Hewlett–Packard 5890 GC equipped with a J&W Scientific capillary column (DB-624) and a FID. A 1-μL sample of the pentane phase was injected into the GC, and the response was compared to the response from standards prepared in pentane. Samples for MEK were collected in 2-mL plastic vials and kept in the freezer until the analysis. HPLC analysis was performed by use of a Spectra Physics HPLC equipped with a Waters 990 Photodiode Array Detector and a reverse-phase Altima C-18 column. The mobile phase used was methanol and phosphate buffer (50 mM KH₂P₄) acidified with 0.1 percent trifluoroacetic acid. The thawed samples were centrifuged to spin down the cell mass. Sample volumes of 100 μL were analyzed.

Experimental procedure: The substrates were chosen to represent constituents in paint were *m*-xylene and *p*-xylene (aromatics), MEK (ketones), and butyl acetate (BA) (esters). Table 16 describes the substrate levels and combinations used in the experiments.

Table 16. Biotreatment of VOC Mixtures in a Lab Scale Reactor

Experiment No.	Substrates	Concentrations in Oil (ppm)	Volume Oil (mL)	Volume Aqueous Phase (mL)
SB1	MEK + <i>m</i> -xylene	500	1000	4000
SB2	MEK + <i>m</i> -xylene	1000	1000	4000
SB3	MEK + <i>m</i> -xylene	1500	1000	4000
SB4	MEK + <i>p</i> -xylene	500	1000	4000
SB5	MEK + <i>p</i> -xylene	1000	1000	4000
SB6	MEK, BA, <i>m</i> -xylene	500	1000	4000
SB7	Oil with MEK, BA, ethylbenzene, <i>m</i> -	Various	1800/2000	4000
SB8	Oil with paint	Various	1800/2000	4000

Results: Treatment of MEK and *m*-xylene in mixture was examined in seven experiments. The system was closed down after the first three experiments due to operational problems. The system was set up and inoculated again, and four more experiments were done with MEK and *m*-xylene.

In the first three experiments, a high removal of *m*-xylene from the oil was observed. In the aqueous phase, *m*-xylene was either not detectable or detectable only at low concentrations. The waste outlet and the air vent from the CSTR were not closed during the first three experiments, which may have contributed to the high removal. Removal of *m*-xylene at rates up to 18 ppm/h was obtained during an 8–10 hour period in the next four experiments. Rapid transfer of MEK from the oil to the aqueous phase was observed in all the experiments. However, the removal of MEK was very low, and an accumulation of MEK in the aqueous phase was observed. After the experiments with MEK and *m*-xylene, *p*-xylene replaced *m*-xylene in the mixture. Removal of *p*-xylene was not detectable. Removal of MEK from the aqueous phase appeared to take place in the range of 5–14 ppm/h.

When mixtures of MEK, BA, *m*-xylene, and *p*-xylene were treated, MEK removal was observed as well. It was not possible to separate *m*-xylene from *p*-xylene in the GC analysis, so total xylene concentration was determined. The rate of removal of the xylenes was 36 ppm/h. BA appeared to be removed as well (standard curve for MEK was used for the GC-analysis).

Treatment of oil containing a mixture of BA, ethylbenzene, *m*-xylene, and *o*-xylene showed only insignificant removal of VOCs from the oil. When oil run in the air treatment system with paint was treated, only xylene removal was observed. MEK and BA appeared only in the oil run with paint for two hours and both compounds were removed immediately from the oil.

5.0 Conclusions

This study was performed to collect data on a novel hollow-fiber membrane-based technology to extract and process VOCs from a dilute stream produced by processes such as paint spray booths. The resultant reactions would form water and CO₂ as a final exhaust stream. This system was at least partly developed during the execution of this project, and the components tested were judged by their capability to produce a system that is economically competitive with such other technologies as thermal afterburners or adsorption systems (e.g., carbon filters). It is concluded that the process science is sound. Under tests/evaluations in which process economics were not considered, VOC removal rates (greater than 70 percent) of certain compounds were measured. Although many of the problems were technical in nature, many could likely be resolved through further research and resource allocations.

5.1 Separation System

No suitable separation module currently exists, and the project's development efforts failed to produce a suitable module to deliver a complete, cost-competitive system for VOC control. Membrane-contactor developers are currently devoting their time and resources to applications they deem more promising with brighter payoff potentials. Equipment size is a problem as well. Microfiber contactor modules are typically developed for small-scale processes, and a module suitable for extracting VOCs from a large paint booth would require manufacturing capabilities that are not currently available. A suitable module could be as much as 20 to 50 times the size of the largest module currently available for any process, and its production equipment would be required to outfit more than just paint booth processing equipment to meet the necessary economies of scale. In addition, radial modules are the most-commonly available, but the separation contactor for paint booth work needs to be a box-type cross-flow module to reduce the air-side pressure drop to reasonable levels.

A number of microporous fibers were tested for their potential to develop appropriate high-performance modules. In early testing, a number of modules with uncoated fibers were tested that produced reasonable results, but pressure balancing between the air side and transfer-fluid side was determined to be economically unfeasible, so modules with coated fibers were pursued as a solution. Pore size as well as coating thickness and consistency are the important parameters for producing the appropriate extraction performance in fibers. The coating must be inert to prevent reactions and such performance detriments as coating swelling or softening. The coating must adhere to the fiber walls. A plasma-polymerized silicone-rubber-coated fiber developed by AMT proved to have good adherence and inertness properties, and this fiber displayed good endurance under a wide range of pressures. The AMT fiber has a greater potential for module development than any other coated

fiber developed or tested in this project. Although testing showed this fiber leaked silicone oil, the coating thickness could have been adjusted to address this problem if more time had been available. Other adjustments are also available to address this problem including coating treatments, pore size, and post-treatment processing steps.

A successful module must be developed simultaneously with testing the intended transfer fluid to be certain of material and physical compatibility. Before modules are developed, potting and module-frame materials must be tested with the intended contact fluid using extended contact times and under the intended operating pressure. Seals such as O-rings or other gaskets must be able to withstand constant immersion in the intended transfer fluid. Octanol attacked many O-ring materials that were used on the Celgard modules during early testing, and the only O-ring found to withstand this fluid was cost prohibitive for production purposes. Subsequently, octanol was found to also swell the coated fibers that were used in the AMT cross-flow separation contactor. This swelling caused bunching and voids in the fiber bundle that resulted in air flow channeling and poor contact. A number of alternate fluids were considered before settling on a replacement for octanol. These alternatives included canola oil and mineral oils, both of which have too many impurities to allow accurate GC determination of extracted compounds, and silicone oil, which would be cost prohibitive in a full-scale facility and would have unknown effects on bugs over a long period. Silicone oil was chosen as an alternative to octanol but, because of time constraints, was not thoroughly tested for partitioning performance, and this may have played a big role in the disappointing removal efficiency test results. In addition, although materials compatibility testing with a higher-viscosity silicone oil produced acceptable results, performance results with a lower-viscosity oil, chosen for its similarity to octanol, resulted in unforeseen problems such as weeping, leaking, and stretched fibers. An optimized module must be closely matched in all characteristics to its extraction fluid. Based on the experience with this project, a fluid or fiber substitution will almost always require a complete return to the beginning of the development cycle.

The AMT cross-flow module has the necessary characteristics for acceptable air-side pressure-drop performance. However, distortion of the fibers caused by small leaks of the thin silicone oil produced uneven contact that counteracted any performance improvements. Data showed that performance from a given arrangement of modules is adversely affected by increased airside flow. Extraction performance drops progressively as the oil absorbs higher quantities of VOCs, but the results of testing may have showed the limited capacity of silicone oil compared to octanol. This conclusion seems particularly obvious when seeing that VOC absorbance dropped quickly during some runs, when the oil was still lightly loaded. On the other hand, increasing oilside flow and pressure enhances performance. This increased performance is, of course, limited by module integrity, and running at higher pressures caused failure of several modules.

5.2 Biotreatment System

5.2.1 Biodegradation Range and Extent

The screening studies, and subsequent growth studies, indicate that several organisms that were isolated are capable of degrading the model compounds tested (*m*-xylene, *p*-xylene, toluene, methyl ethyl ketone, butyl acetate). As one would expect, no single organism was capable of simultaneously degrading all of the compounds used during the project. Therefore, a consortium of organisms was used to effect degradation of VOC mixtures. The majority of the work performed focused on two organisms, designated M1 and X1. These organisms were isolated utilizing aliphatic and aromatic substrates, respectively.

The degree of degradation exhibited by the organisms used in the study was significant. Between the two organisms, all of the compounds could be reduced to levels below 250 ppb in an aqueous phase. These levels were exhibited in experiments GS2–GS10, GS14, FS3, and FS5–FS8. In every case, this VOC level represented greater than 99 percent reduction in the amount of compound present initially.

5.2.2 Problems Arising from Metabolic Regulation

The experimental results obtained indicate that concurrent degradation of aromatic and aliphatic VOCs in a single bioreactor is problematic. Cultures containing M1 and X1 (individually or in combination) exhibited roughly concurrent degradation of the aromatic compounds, followed by degradation of the aliphatics. Table 17 indicates those experiments where concurrent (or nearly so) degradation or aromatic–aliphatic sequential degradation was observed and identifies the compounds involved.

Table 17. Concurrent Degradation

Experiment No.	Organism(s)	Compounds
GS3	X1	Toluene, <i>m</i> -xylene
GS5	M1	Toluene, MEK
GS6	M1	<i>m</i> -Xylene, MEK
GS7	M1	Toluene, <i>m</i> -xylene
GS9	M1 AND X1	Toluene, MEK
GS10	M1 AND X1	Toluene, <i>m</i> -xylene, MEK
GS14	X1	<i>m</i> -Xylene, <i>p</i> -xylene

Ethylbenzene was found to have a predominantly, but not exclusively, inhibitory effect on culture

growth and biodegradative activity, as indicated directly by the results of experiment GS13 and as can be inferred from the results of experiments SB7 and SB8. The results from GS13 indicate that ethylbenzene stimulates growth to a small degree at aqueous phase levels below 100 ppm, but a level of 150 ppm prematurely terminates cell growth. The low rate of degradation of aromatic compounds exhibited in experiments SB7 and SB8 (ethylbenzene present) relative to results from experiments SB3, SB5, and SB6 (ethylbenzene absent) suggests that aqueous-phase ethylbenzene levels as low as 40 ppm might have an inhibitory effect on aromatic degradation in biofilm cultures. This is, however, a supposition; further testing is necessary before this can be reliably concluded. Fortunately, no such inhibition was noted for degradation of butyl acetate or MEK.

5.2.3 Treatment Strategy

Given the sequential nature that was observed for aromatic/aliphatic degradation, the strategy was adopted to circulate the aqueous phase of the biofilm reactor through a continuously stirred tank reactor containing primarily M1 (the aliphatic degrader). As indicated in experiments SB2 through SB6, this strategy is quite successful in concurrently reducing aliphatics (MEK and/or butyl acetate) and aromatic compounds (*m*- or *p*-xylene) in the oil phase. This behavior was indicated by staged biotreatment systems with fresh films (SB4, 6) and films regenerated following EDTA-induced sloughing (SB3, SB5).

5.2.4 Implementation

The flat-sheet and staged-bioreactor studies indicate that “bioextraction” of VOCs from the carrier fluid occurs at rates sufficient to maintain active cell growth and activity. These studies also indicate that the hollow-fiber membrane units available to this project had inadequate surface area to effectively treat the carrier fluid in anything approaching real time. The hollow-fiber membrane units do, however, offer effective contacting of the biofilm with the carrier fluid. It would appear that the next steps in evaluation of this configuration would involve (1) identifying an effective degrader of ethylbenzene and (2) designing a membrane contactor that would enable sampling of the biomass so that comparisons can be made between the flat-sheet results (where biomass can be sampled directly) and the hollow-fiber unit performance.

6.0 Recommendations

The technology developed as a result of this project must be technically and fiscally sound before a decision will be made for future full-scale implementation. Although the technology has been demonstrated to have technical promise or potential, no results have been produced that warrant further consideration and study until manufacturing techniques for membrane modules advance enough to allow the cost-effective fabrication of low-pressure-drop, high-efficiency, leak-free modules. The potential cost and environmental benefits of such a system do warrant consideration of further basic development projects aimed at improved fibers, coatings, stripping fluids, and module designs.

Future efforts should concentrate on fiber and module development. Many options are available for fiber materials and for coatings (see AMT response), and more are being developed each year, usually for some specific application that suddenly becomes financially promising. Module construction is also undergoing groundbreaking development in many other applications.

Paints are also being reformulated, and this will make specific module development more difficult, especially considering the difficulty experienced in identifying paint constituents. Future work should pay particular attention to the great difference between common paint constituents, such as industrial-grade xylenes and pure compounds, when performance testing. The use of a total hydrocarbon analyzer through each phase will more clearly establish whether performance goals are being achieved or if many compounds are escaping notice.

6.1 AMT Recommendations

Applied Membrane Technology, Inc.'s objective was to develop low-pressure-drop cross-flow hollow-fiber membrane modules for use in the MBT system intended for high volumetric flow rates containing low contaminant concentrations of fugitive target compounds. To provide suitable low-pressure-drop modules within the project time constraints, both module fabrication and membrane composition needed to be based as much as possible upon known parameters of module construction and chemical formulation. In other words, a thorough investigation of alternative materials of construction that might be more suitable was not feasible during AMT's period of involvement.

AMT's module design was based on a previous project for the US Navy for use in a low-pressure-drop seawater application. This design was adapted for the ARCADIS VOC air project with several minor alterations to make it more compatible for air-stripping applications. AMT successfully designed and built a winding fixture that could wind four cross-flow membrane modules at a time. (Scale-up to larger volumes would be straightforward based on this design). The modules produced

using this design yield a very low air side pressure drop as intended. The module housings were constructed from polycarbonate due to the need to rapidly tool fixture parts and module components. Other module housing materials suitable for long-term applications could be utilized in the future.

The hollow-fiber membranes proved to be a more-problematic issue. Preliminary testing and evaluations of membrane fibers and prototype modules utilizing plasma-polymerized, silicone-coated, polypropylene fibers indicated adequate flux of VOCs and tolerance for contact with silicone oil up to 35 to 40 psi. AMT lab evaluations of octanol stripping agents ruled them out due to excessive swelling and distortion of polypropylene membrane substrates supplied by all vendors.

Membrane compositions for use with silicone-oil stripping agents could be made utilizing stronger polypropylene substrates produced by Celgard US or AKZO Membrana, although they will exhibit some degree of swelling depending on pressure, temperature, and the nature of the membrane top coating. AMT could place copolymer coatings, such as silicone/Teflon or silicone/propylene, onto these microporous substrates instead of the straight silicone membrane.

The latter copolymer compositions have shown higher resistance to oil permeation and swelling effects in other AMT lab projects and during evaluation of flat-film samples conducted by outside research groups. The ability to tailor the coatings' chemical composition offers potential avenues for future improvements. Other groups encountered similar problems of oil and solvent swelling/permeation during the successful development of solvent extraction from oil in the de-waxing process performed by petroleum companies. Mobil Oil and Texaco use several commercial units based on flat membranes. AMT can make hollow-fiber versions of similar copolymers, which may merit investigation for applications such as the MBT system. AMT would need to evaluate a series of potting compounds and determine appropriate potting techniques for assembling bundles of such coated fibers because adhesion becomes more difficult as the concentration of Teflon or polypropylene increases in the membrane coatings. It is a doable proposition, but the time constraints of this project would not have allowed for such trials.

In addition, AMT could evaluate both polymeric and ceramic non-propylene-based substrates. For example, new ceramic-based hollow fibers of dimensions comparable to conventional microporous membranes and coated with a silicone/PTFE copolymer membrane via plasma polymerization may offer the ideal membrane composition for membrane-mediated extraction of VOCs. The ceramic materials would tolerate broad temperature and pressure regimes and exhibit no swelling behavior, and the membrane coatings could be tailored to optimize VOC flux while restricting oil permeation. The objective of such an endeavor would be to raise the operating window of the cross flow module so that higher pressures (i.e., faster liquid sweep rates) could be utilized to enhance module VOC-stripping performance as well as to fix the hollow fibers in place for air flow distribution without

later shifting due to swelling, as observed in the current units.

In summary, the general design and method used to fabricate the cross-flow membrane modules was found to be suitable for producing the low-pressure-drop units. More adequate allocation of resources in terms of time and research expenditures directed at optimizing the hollow-fiber substrate/coating composite formulation may result in superior membrane performance, which, in turn, would provide a more-economic and commercially viable operating window for the MBT process.

Appendix A

**Literature Search
and Review**

The success of the VOC treatment technology we are developing is dictated by the performance of the separation and biotreatment modules. Certain design and operational criteria are recognized as essential to the efficient and economical operation of each contactor. For the air/VOC separation module, these criteria include the following:

- High surface-area-to-volume ratio
- Membrane composition and configuration to maximize VOC transfer
- Membrane configuration to minimize leakage of transfer fluid into air stream
- Module design to minimize airside pressure drop
- Possibility for commercial availability of module

For the bioreactor module these criteria include the following:

- High surface-area-to-volume ratio
- Membrane configuration to minimize leakage of transfer fluid into aqueous stream
- Design and operation to minimize biofouling of the aqueous side
- Maximize degradative activity of biofilm
- Capability to rapidly degrade a wide variety of VOCs

In consideration of these issues, the following extensive literature search was undertaken to guide the subsequent development of the process.

AIR/VOC SEPARATION MODULE

Module Type

Although membrane-based gas separation was first commercialized in 1977 for the enrichment of oxygen from air, the predominant applications currently are for the production of high-purity (99.95%) and medium-purity (95–99.5%) nitrogen (Prasad, 1994), CO₂ removal from natural gas (McKee, 1991), and hydrogen purification for recycle (Shaver, 1991). All of these processes employ asymmetric or composite polymer membranes (Stern, 1994). These applications have come on the heels of 20 years of intensive research that saw the development of asymmetric membranes that exhibited high fluxes (Loeb, 1963), a method for the synthesis of robust hollow fibers (Vos, 1969), and a method for the casting of ultrathin, high-permeability, nonporous polymer films onto existing membranes (Ward, 1976) [subsequently improved upon and commercialized by Monsanto (Henis, 1981; Henis, 1980)]. Commercial membrane-based nitrogen production processes, for example, predominantly utilize hollow-fiber membrane configurations instead of plate-and-frame or spiral-wound. The rationale for this choice is clear when considering the relative membrane module areas. Koros and Fleming report that membrane module areas for the three configurations are: 100–150 ft²/ft³ for plate-and-frame modules, 200–250 ft²/ft³ for spiral-wound, and 2000–4000 ft²/ft³ for hollow-fiber modules (Koros, 1993). The advantageous surface-to-volume ratio attained by hollow-fiber systems was a major factor in our selection of this configuration for our modules.

Membrane Composition

Membrane transport

To select among the plethora of materials available for membrane construction, it is important to first understand the molecular basis of flux through porous and nonporous polymeric materials. Because essentially all commercial gas-separation membrane systems utilize nonporous membranes, the

description of transport through strictly porous materials will be abbreviated. Flux is the rate of transport of a chemical species (also referred to as the penetrant) through a given membrane or pore-filling material. Flux is determined by the chemical potential gradient of the transported species across the membrane, the membrane thickness, and in the case of nonporous membranes, the solubility of the species in the membrane material. The mechanism of species flux through nonporous material has been generally described as solution–diffusion (Koros, 1989; Koros, 1991) and depends upon the solubility (or condensability) and the diffusivity of the species in the polymer.

The chemical potential gradient is represented by the partial pressures of the species on either side of the membrane for gas–gas separations or, in the case of a gas–liquid separation, the "effective" partial pressure of the species on the liquid side of the membrane. An intrinsic property of polymeric material relative to species transport is the permeability (P_A), which is "a parameter equal to the pressure-and-thickness-normalized flux" (Koros, 1993), as shown in Eq. 1:

$$P_A = (\text{flux of } A \text{ per unit area})/(\Delta p_A/d_m) \quad (1)$$

where Δp_A is the partial pressure gradient of species A across the membrane and d_m is the membrane thickness. Permeability is a direct measure of the ease of transport of the species through the membrane, and it can be written as the product of the solubility coefficient, S_A (a thermodynamic parameter) and the diffusion coefficient D_A (a kinetic parameter);

$$P_A = (S_A) (D_A) \quad (2)$$

These coefficients can themselves be complex functions of many variables, including identity and concentrations of current and past sorbed species as well as temperature (Koros, 1989; Koros, 1991). What is of importance to those seeking to separate two gas-phase species (A, B) is the separation factor, or selectivity, (α_{AB}), which is defined in terms of the mole fractions of the two species (y_A, y_B) upstream (subscript 1) and downstream (subscript 2) of the membrane.

$$\alpha_{AB} = \frac{y_{A2}/y_{B2}}{y_{A1}/y_{B1}} \quad (3)$$

The separation factor can also be written in terms of the permeabilities of the two penetrants and the relative partial pressure driving forces (Ashworth, 1992; Koros, 1993; Stern, 1994):

$$\alpha_{AB} = \frac{P_A}{P_B} \times \frac{\Delta p_A/p_{A1}}{\Delta p_B/p_{B1}} = \frac{D_A}{D_B} \times \frac{S_A}{S_B} \times \frac{\Delta p_A/p_{A1}}{\Delta p_B/p_{B1}} \quad (4)$$

Written in this manner, the separation factor can be seen to have contributions derived from penetrant solubility (S_A/S_B) and penetrant mobility (D_A/D_B). Selective solubility is the controlling factor in processes involving the separation of vapors from gases, such as VOC removal from air (Baker, 1987; Watson, 1990; Lund, 1996; Deng, 1998). The motion of polymer segments in the membrane controls mobility selectivity. As these segments move, free volume becomes available to the penetrant and it "hops" from one intersegmental free volume to another (Kumins, 1968; Frisch, 1983; Zielinski, 1992). The frequency of these movements is affected by membrane temperature (Kulkarni, 1983), by the size of the side chains along the polymer backbone, and by whether the polymer is glassy or rubbery (above or

below the glass transition temperature for that polymer). This theory has been used successfully to describe the permeability of organic vapors in several rubbery polymers (Fujita, 1968; Suwandi, 1973), most particularly silicone rubber (Sok, 1992) or poly(dimethylsiloxane) (PDMS).

Membrane experimental configurations

Use of membranes to separate VOCs from a contaminated stream has taken two primary forms: pervaporation and vapor-phase extraction. In pervaporation, a contaminated aqueous phase contacts the shell side of a microporous hollow fiber, which has been coated with a nonporous thin film, most often PDMS. A vacuum is drawn, or a carrier gas flows on the tube side of the membrane, and the VOCs permeate through and evaporate from the membrane. Vapor-phase extraction, on the other hand, generally involves a contaminated gas stream with a vacuum or extraction fluid on the other side of the membrane. The driving force in these cases is the same as described above, the chemical potential gradient caused by low downstream penetrant concentration.

Porous membranes

When a gas–vapor mixture is made to flow through a porous solid medium, the condensable species (vapors) have much higher transport rates than the noncondensable species (gases). This phenomenon is the result of several transport mechanisms, including adsorbed flow (Carman, 1952) and capillary condensation (Rhim, 1975; Lee, 1986; Qiu, 1991). For the condensable gas, capillary condensation can occur on the insides of the pores at a pressure much less than the ordinary condensation pressure (or at a concentration much less than normal). Once condensed, the transport of the condensate through small pores can be regarded as viscous flow, and this flow blocks the transport of the noncondensable gas through the pores. A mathematical treatment of these phenomena was presented by Qiu and Hwang (1991) and compared to experimental results using a porous glass membrane.

Nonporous membrane materials

A significant number of investigations have focused on the effect of polymer modifications on transport properties for both glassy and rubbery polymers. Two generalizations can be made regarding the results obtained:

1. Permeability and selectivity exhibit an inverse relationship.
2. Rubbery polymers exhibit high permeability and low selectivity; glassy polymers exhibit high selectivity.

Several exceptions to these "rules" do exist, and it is instructive to investigate more closely the literature regarding glassy and rubbery polymers separately.

Glassy Polymers

Generally, these polymers exhibit higher selectivity and lower permeability than rubbery polymers. However, PTMSP (poly [(1-trimethylsilyl)-1-propyne]), a polyacetylene which has a repeating structure of $[-(\text{CH}_3)\text{C}=\text{C}(\text{Si}[\text{CH}_3]_3)-]_x$, is a glassy polymer that has been found to have roughly ten-fold higher permeability than PDMS with only somewhat lower selectivity (Masuda, 1983; Takada, 1985; Masuda, 1988; Ichiraku, 1987). Prior to these results, PDMS was found to have the highest permeability of any nonporous polymer. The high permeability of PTMSP is attributed to the bulky side groups ($-\text{Si}[\text{CH}_3]_3$) which generate a large free-volume fraction (estimated to be 0.20–0.27) (Platé, 1991) for penetrant diffusion. Unfortunately, since glassy polymers are non-equilibrium materials, their excess free volume

tends to decrease over time and is highly dependent on the processing history of the polymer. As such, unmodified PTMSP is not suitable for long-term commercial applications.

Significant effort has also been put forth to investigate the substituted polyacetylenes, including analogs of PTMSP, to determine whether achieving even higher permeabilities with little loss of selectivity and with enhanced stability is possible. Early efforts, summarized by Odani and Masuda (Odani, 1992), indicate that polyacetylenes with bulky substituents tend to have the highest permeabilities and that the substitution of long *n*-alkyl groups for the silyl group, or long alkyl groups for a methyl group on the silyl group, greatly reduces the permeability of the polymer.

More-recent efforts by Nakagawa and co-workers have investigated the modification of PTMSP by bromination (Nagai, 1994) and by copolymerization (Nagai, 1997). Brominated PTMSP also exhibited a time-dependent decline in gas permeability for a number of gases (O₂, N₂, CO₂, C₃H₈). However, the decline was less pronounced than exhibited by PTMSP, and once it restabilized, consistent permeability was observed throughout a 175-day period (Nagai, 1994). Much greater success was achieved by copolymerization or blending of PTMSP with poly(1-phenylpropyne) (PPP), a glassy polymer with excellent stable gas permeability but lower permeability than PTMSP (Nagai, 1995). PPP concentrations up to 10% in either blended or copolymerized form caused less than an order-of-magnitude decrease in permeability and essentially complete stability over a 30-day period.

Work similar in breadth and focus has been underway for polyimides, poly(ether imides), polypyrrolones, poly(amide imides), polycarbonates, polysulfones, cellulose acetate and poly(phenylene oxide). While many of these studies show promise for development of high-performance vapor-separation materials, few are sufficiently advanced to warrant detailed consideration. Interested readers are directed to Stern (1994) for a review of early literature in these areas. We will deal directly with polysulfones with specific mention of poly(alkylsulfone) (PAS-16).

In general, polysulfones are glassy at room temperature and have the high penetrant size selectivity characteristic of glassy polymers. However, PAS-16 is a rubbery polysulfone copolymer of hexadecene and sulfur dioxide as shown in Figure 1. It exhibits some side chain crystallinity at room temperature; the degree of which is dependent upon the thermal processing of the polymer. This makes the permeability of PAS-16 history-dependent, which is atypical of rubbery polymers (Singh, 1997).

Figure A-1. PAS-16 Repeating Unit

Extensive characterization of PAS-16 for permanent gases (O₂, N₂, H₂ and CO₂) indicates that the PAS-16 behaves as a typical rubbery polymer. However, a comparison of permeabilities for PAS-16 and PDMS indicates that permeability in PAS-16 is roughly one order of magnitude lower than that in PDMS (Gray, 1976; Gray 1984; Singh, 1997), which makes it the next-most permeable-polymer given the high

permeability of PDMS. The permeability of PAS-16 to organic vapors is likewise high, though some crystallinity is manifested in these experiments, with permeability decreasing dramatically upon first exposure to toluene (induces local crystallization) and then remaining constant for a given penetrant (toluene, *n*-hexane, acetone and methanol) at different partial pressures (Singh, 1997). The relative permeability of the top two penetrants (toluene and *n*-hexane) is temperature dependent, with *n*-hexane permeability highest under 40 °C and toluene permeability highest at higher temperatures (Singh, 1997). This polymer behaves as do the rubbery and ultrahigh-free-volume glassy polymers (PTMSP, for example) regarding permeability dependence on penetrant solubility (Freeman, 1997), and as such, it deserves further investigation to establish its suitability for commercial application.

Rubbery Polymers

PDMS $(-(\text{CH}_3)_2\text{SiO}-)_x$ has incredibly high permeability to a wide variety of gases; more than an order of magnitude greater than the nearest polymer (with the exception of PTMSP, as previously described). The high permeability of this polymer is generally accompanied by low overall selectivity for low-molecular-weight gases. The high permeability of PDMS is attributed to the flexibility of the siloxane $(-\text{SiO}-)$ linkages of this polymer. Research with this polymer has focused on modifications that exhibit higher selectivity without sacrificing permeability. Results analogous to those obtained for PTMSP were obtained:

1. Bulkier functional groups on the side chain (replacing a methyl group) decreased permeability by increasing chain stiffness (Stern, 1987; Lee, 1988). These substituents act by reducing the diffusivity of the penetrant in the polymer, not by reducing solubility.
2. An inverse relationship holds between permeability and selectivity.
3. Substituents that induce formation of crystalline domains greatly reduce permeability (Stern, 1987).
4. Specific interactions between the penetrant and the polymer that increase solubility dramatically increase the permeability of the polymer to that penetrant (Ashworth, 1991).

The overall selectivity of highly permeable silicone polymers is a function of the solubility selectivity (S_A/S_B), not the mobility selectivity (D_A/D_B) (Stern, 1987). Given this fact, and in light of item (4) above, a potentially effective method for increasing selectivity in silicone polymers, without impairing permeability, is to substitute functional groups that interact specifically with selected penetrants.

Membrane Configuration

Composites versus single-polymer (simple) membranes

The transport mechanisms of gases through composite membranes involve two major diffusional pathways, as shown in Figure A-2 (adapted from Kimmerle, 1991).

Path 1 runs through the nonporous top layer (thin film) polymer, which generally exhibits some selectivity, then into the pore space of the basement membrane. Path 2 runs through the thin film and then through the basement membrane polymer (substructure) itself before reaching a pore space. The basement membrane material is usually selected to provide structural support for the thin film and is of high porosity to minimize the contribution of basement membrane resistance to the overall resistance to transport of the penetrant. The key parameters determining the flux through composite membranes under a given driving force can be developed in the following manner.

Figure A-2. Two Pathways for Transport Through a Composite Membrane

The volume flux of penetrant, J , can be related to membrane structure by substitution of the appropriate terms into the general relationship that flux is equal to the product of the driving force and area, divided by the resistance to transport. For path 1, this equation is (Pinnau, 1988):

$$J_i^{L,P} = \frac{(\Delta p_i \times A^P)}{\left(\frac{d^L}{P_i^L} + \frac{d^P}{P_i^P} \right)} \quad (5)$$

where P_i^x is the permeability of penetrant i in membrane component x , where $x = L$ denotes the top layer, $x = P$ denotes the pore and, in equation (6), $x = S$ denotes the membrane substructure material. A^P denotes the surface area of the pores and d^x denotes the thickness of the particular membrane component x ($=L, P$). For path 2, transport can be expressed in the following way (Henis, 1981):

$$J_i^{L,S} = \frac{(\Delta p_i \times A^S)}{\left(\frac{d^L}{P_i^L} + \frac{d^S}{P_i^S} \right)} \quad (6)$$

where A^S denotes the surface area of the substructure, which is equal to the total membrane surface area, A^M , minus the pore area, A^P . The porosity of the membrane ε can be expressed as

$$\varepsilon = \frac{A^P}{A^M} \quad (7)$$

The total flux of penetrant i through the membrane is given by

$$J_i^M = J_i^{L,S} + J_i^{L,P} \quad (8)$$

An expression for the total volume flux (per unit area), $J_{i,A}$, can be expressed by combining equations (5-8) to give:

$$J_{i,A}^M = \left\{ \varepsilon \left(\frac{d^L}{P_i^L} + \frac{d^P}{P_i^P} \right)^{-1} + (1 - \varepsilon) \left(\frac{d^L}{P_i^L} + \frac{d^S}{P_i^S} \right)^{-1} \right\} \Delta p_i \quad (9)$$

There are three scenarios to be considered using this equation relative to what controls the performance of the composite membrane: (1) *top-layer* controlled, (2) support-structure controlled, and (3) mixed-flux control. Kimmerle concludes the following regarding membrane configuration:

If the transport properties of a membrane are determined by the selective top layer it can be optimized in terms of its flux and selectivity by preparing a support structure which has the highest possible porosity and permeability in the pore structure. The permeability of the selectivity top layer should furthermore be as high and its thickness as low as possible. (Kimmerle, 1991)

This conclusion is endorsed by a large number of practitioners in the field (Koros, 1993; Parthasarathy, 1994; Stern, 1994; Prasad, 1994; Nagai, 1997; Zhu, 1983; Blume, 1990; Bessarabov, 1996; Das, 1998; Poddar, 1996b; Cha, 1996) who have evaluated single polymer and composite membranes for gas separation and VOC removal from liquid and air streams.

In a recent review of commercial air separation processes, Prasad and co-authors list the development of ultrathin barrier layers as one of the key technical innovations in the commercial development of membranes in air separation. "The discovery by Loeb and Sourirajan (Loeb, 1963) of integrally skinned, high-flux asymmetric membranes was essential in transforming membranes to a technology of significant commercial interest" (Prasad, 1994). Ashworth provides an excellent illustration of the direct benefit of composite membranes using the separation of H₂ from CO as the goal and polysulfone and silicone rubber as the membrane materials under consideration (Ashworth, 1992). The following data are taken from his paper.

Table A-1. Effect of Membrane Composition on Permeability and Selectivity

Polymer	Permeability (cm ³ (STP)-cm/cm ² -sec-cmHg)		$\alpha_{H_2/CO}$
	CO	H ₂	
Silicone rubber (SR)	5.2×10^{-8}	2.5×10^{-8}	2.1
Polysulfone (PS)	1.2×10^{-9}	3.0×10^{-11}	40
SR/PS (99:1) ^a	3.65×10^{-8}	2.68×10^{-9}	13.6
SR/PS (91:9) ^a	1.08×10^{-8}	3.29×10^{-10}	32.8

^a The ratio denotes the relative thicknesses of the two polymers in a bilayer composite.

Obviously, the productivity of the composite membrane is nearly an order of magnitude higher than that achieved by the pure polysulfone membrane (approximately 80% selectivity, ninefold increase in H₂ permeability). Experiments involving the separation of dichloroethane, chlorobenzene and chloroform from water across polyvinyl acetate, PTFE, or polysulfone membranes (simple or composite) also support such a conclusion. In all cases, the separation factor was at least an order of magnitude higher for the

composite membranes than the equivalent simple membrane (Zhu, 1983). In addition, the composite membranes exhibited greater structural stability (Zhu, 1983).

Blume (1990) compared the permeability and separation factor for trichloroethane, ethyl acetate, acetone and ethanol in a pervaporation through PDMS and PDMS/polyolefin composite membranes. As expected, the PDMS membrane exhibited permeabilities that were an order of magnitude greater than those achieved by the PDMS/polyolefin composite, but the separation factors of the composite were an order of magnitude greater than that of the PDMS membrane so that the flux of a penetrant through the membranes was equivalent, and the concentration of penetrant in the downstream gas was much higher for the composite membrane (Blume, 1990).

Film composition

Baker and co-workers at Membrane Technology & Research Inc. (1987) investigated eight membrane materials for their permeabilities to acetone, toluene, octane, trichloroethane and nitrogen. Each membrane was a flat sheet, cast to a thickness of 25–50 μm , and evaluated at 40 °C. Figure A-3 is taken from Baker (1987) and presents the relationship between toluene permeability and selectivity when toluene was removed from a nitrogen gas stream by pervaporation. Note that the permeability of PDMS (silicone rubber) is nearly matched by that of chloroprene (Neoprene™), which exhibits a higher selectivity than PDMS. Figure A-4, which presents equivalent data for acetone, indicates that silicone rubber is not uniformly the best rubberized membrane for organic compound permeability (Baker, 1987).

Figure A-3. Toluene Permeability vs. Selectivity For Toluene Over Nitrogen

Figure A-4. Acetone Permeability Vs. Selectivity For Acetone Over Nitrogen

Inner versus outer films

The question of placement of the thin film in a composite membrane relative to the liquid and gas phases is an important one. If the film is on the same side of the membrane as the liquid, then the pores will be gas-filled, and vice versa. Gas-phase diffusivities are several orders of magnitude larger than liquid-phase diffusivities (Semmens, 1989). This is significant because the resistances-in-series model has been found to be applicable to composite membrane transport. If one considers the composite membrane and the affiliated resistance, shown in Figure A-5, one finds four potential resistances, through fluid boundary layers, R_{f1} and R_{f2} , through the film, R_F , and through the porous membrane, R_{PM} . Total resistance to transport, R_T , is equal to:

$$R_T = R_{f1} + R_F + R_{PM} + R_{f2} \quad (10)$$

Figure A-5. Transport of Penetrant Through Different Resistances of a Composite Membrane

Studies of the transport of organics through uncoated pervaporation membranes indicate that the liquid-side boundary-layer mass transfer resistance is a significant fraction of the total mass transfer resistance (Raghunath, 1992). In some cases where nonporous films coat the fiber, the film resistance dominates so that all other resistances can be neglected, as was the case reported for transport of methylene chloride across a PDMS/polyethylene composite and absorption into either silicone oil 200 fluid or Paratherm NF mineral oil (Poddar, 1996a). However, using the same experimental system, the film resistance represented only 64% of the total resistance to transport of acetone (Poddar, 1996a). In that case, the porous membrane and liquid boundary layer were found to contribute significantly to the overall resistance. The resistance could have been lowered had the pores been filled with gas (Das, 1998; Semmens, 1989) instead of oil, a point made clearly by Semmens et al. (1989). In a study of pervaporation of several organic compounds (CCl_4 , C_2Cl_4 , C_2HCl_3 , CHCl_3 , $\text{C}_2\text{H}_3\text{Cl}_3$) in a vapor phase across microporous polypropylene fibers without a coating film, Semmens found that the gas-filled membrane pores offered negligible resistance to transfer (Semmens, 1989).

Cha et al. (1997) also studied vapor-phase pervaporation (gas/vapor mixture on one side on the membrane, vacuum on the other) where the feed side was varied from the film side to the non-film side of a PDMS-coated polypropylene hollow fiber. Surprisingly, the fastest permeation rates were achieved with the gas/vapor mixture exposed to the non-skin side of the composite membrane (tube side in this case). This was attributed to condensation of the vapors within the pores and decreased pressure drop within the pores (Cha, 1997).

Sirkar and co-workers (Das, 1998) studied trichloroethylene (TCE) removal from water utilizing hydrophobic, microporous, polypropylene, hollow fibers (Celgard™ X-10) with a plasma-polymerized silicone coating on the fiber outside (shell side) in pervaporation studies. The aqueous stream was fed through the fiber (tube side) instead of the traditional shell-side contacting. TCE removal was found to be significantly lower when the feed was on the shell side compared to tube-side feed. The most plausible explanation proffered involved bypassing of the fluid flow on the shell side given the tight packing of the fibers and the relatively low fluid velocity. Such shell-side bypassing has been observed with similar modules used for liquid–liquid extraction (Tompkins, 1993).

VOC Transport

Solubility

Preferential solubility of different penetrants in the membrane determines the permeability and selectivity of the membrane. High penetrant–membrane affinity leads to high permeation rates. Several investigators have evaluated the effect of membrane composition on separation and permeation performance. It has generally been established that penetrants with solubility parameters close to that of the membrane material sorb to the polymer and permeate more rapidly than those penetrants with solubility parameters significantly different from the membrane (Zhu, 1983). Table A-2 contains solubility parameters (δ) for several common polymers and organic compounds. The solubility parameter, δ , is defined in Eq. (11):

$$\delta = \left(\frac{\Delta U^V}{V^L} \right)^{.5} \quad (11)$$

Where ΔU^V is the energy of complete vaporization of the liquid, and V^L is the liquid molar volume. Table A-3 indicates the separation factors (α) achieved for different penetrant/membrane pervaporation systems.

Table A-2. Solubility Parameters (Zhu, 1983)

Compound	δ (cal/cm ³) ^{.5}	Compound	δ (cal/cm ³) ^{.5}
Chloroform (CF)	9.3	PTFE	6.2
chlorobenzene (CB)	9.5	polyvinyl acetate (PVAc)	9.3
1,2 dichloroethane (DCE)	9.8	polysulfone (PSF)	10.2
water	23.4	cellulose acetate (CA)	11.5

Table A-3. Separation Factors for Membrane/Penetrant Pervaporation Systems (Zhu, 1983)

Polymer	α		
	DCE	CF	CB
PTFE		5–19	7–16
PVAc		50–75	46–55
PSF		3–10	1–8
CA		1	N/A

Watson and Payne (1990) evaluated the separation factor and permeability of silicone rubber membranes (0.2 mm thickness) for *n*-alcohols (C₁–C₁₀) and a variety of other organic compounds in dilute aqueous solutions using pervaporation. The separation factor (α) was shown to rise monotonically with alcohol chain length (Watson, 1990), as shown in Table A-4. Included in Table A-4 are diffusion coefficients, *D*, measured at 80+ 3 °C in a 0.8 mm thick silicone rubber membrane.

Table A-4. Separation Factor Dependence on Chain Length for *n*-Alcohols

<i>n</i> -Alcohol	Feed concentration (%v)	α	<i>D</i> (x10 ⁻¹⁰ m ² -sec ⁻¹)
Methanol	1.0	9	10.0
Ethanol	1.0	17	7.1
Propanol	1.0	67	6.2
Butanol	1.0	74	5.5
Hexanol	0.5	1050	4.2
Octanol	0.05	3100	3.9
Decanol	0.005	5000	2.5

For pervaporation, since the downstream pressure of the penetrant is essentially zero, Eq. (4) reduces to

$\alpha_{AB} = \frac{D_A}{D_B} \times \frac{S_A}{S_B}$. The increase in separation factor exhibited by the *n*-alcohols in the face of declining diffusivities, shown in Table 4, indicates that the increase in separation factor measured through the

silicone rubber membrane is driven by the selectivity factor, $\frac{S_A}{S_B}$, not the diffusivity factor, $\frac{D_A}{D_B}$. The

results of further investigations are presented in Table A-5. The solubility factor (*A*) in Table 5 is based on the Scatchard–Hildebrand activity–solubility equation (Hildebrand, 1970), which allows the development of a relationship for the partition coefficient, *P*, of component *i*, between an aqueous solution (*w*) and a membrane (*m*), as defined in Eq. (12):

$$P = \frac{C_i^m}{C_i^w} = \text{const} \times e^{\left\{ \left(\frac{\bar{V}_i}{RT} \right) A \right\}} \quad (12)$$

$$A = \left[(\delta_w - \delta_i)^2 - (\delta_m - \delta_i)^2 \right] \quad (13)$$

As the solubility factor *A*, defined in Eq. (13), increases, the partitioning of component *i* into the membrane also increases.

Table A-5. Separation and Solubility Factors for a PDMS Membrane Pervaporation System

Compound	Feed concentration (%v)	α separation factor	<i>A</i> (cal/cm ³) solubility factor
Methanol	1.0	9	-2.3
Ethanol	1.0	17	5.0
Phenol	1.16 ^a	97	24
Acetone	1.0	170	35
Octanol	0.05	3100	64
Nitrobenzene	0.1	4200	62
Chloroform	0.01	15,000	50
Benzene	0.1	20,000	69
Toluene	0.01	36,000	81
Ethylbenzene	0.01	43,000	97

^a Percent mass

The data presented in Tables A-4 and A-5 indicate that, for poly(dimethylsiloxane) (PDMS), solubility selectivity is the controlling factor in determining permeability, a conclusion which is in agreement with other findings (Bell, 1988).

Operating Conditions

Leemann (Leemann, 1996) investigated the temperature and concentration dependence of the permeability of pure PDMS hollow fibers (OD approximately 1.0 mm, ID approximately 0.85 mm, length = 250 mm) operated as pervaporation membranes. The permeabilities for toluene, *p*-xylene, ethyl acetate, MEK, acetone and ethanol vapors decrease with increasing temperature, exhibiting Arrhenius dependence on temperature (Leemann, 1996). This is due to the strongly exothermic nature of absorption of organic vapors into PDMS (Leemann, 1996). Similar temperature dependence was noted for pervaporation of carbon dioxide and methane through polypropylene and PDMS membranes coated with fluoropolymer films (Oh, 1996), acetone and ethanol permeation through microporous glass (Qiu, 1991), and acetone pervaporation through silicone rubber (Deng, 1998)

Penetrant concentration, as indicated by the partial pressure of the penetrant in the vapor phase, has a greater effect upon permeability through PDMS at lower temperatures (below 50 °C). At low feed-gas temperatures, permeability increases with penetrant partial pressure, presumably due to increasing diffusivity due to polymer swelling (Leemann, 1996). This was noted specifically for PDMS–polypropylene composite membranes with permeation of toluene, methanol, acetone and methylene chloride (Cha, 1997). However, studies of gas–liquid pervaporation systems indicate that as organic concentration increases in the aqueous feed phase, the separation factor falls dramatically for silicone rubber membranes (Seok, 1987; Ishihara, 1986; Leeper, 1987). The separation factor has also been found to decrease with increasing aqueous phase concentration of the solute until a limiting value is reached for a wide variety of organic compounds (Zhu, 1983; Watson, 1990; Seok, 1987).

The picture is rendered more complex when multiple organic vapors are considered. As different penetrants exhibit different permeation rates, the more slowly permeating compound will build up on the upstream membrane surface (Feng, 1992; Haraya, 1987; Psaume, 1988) diluting the faster penetrant at the membrane surface and resulting in lower permeation rates for the faster penetrant. A parametric study was undertaken to investigate the significance of this phenomenon, termed concentration polarization (Feng, 1992). It was determined that (1) concentration polarization is significant for highly permeable and selective membranes, (2) separation is effective for low vapor content, and (3) for highly selective membranes, variable permselectivity has little effect on permeant concentration but greatly influences permeant flux (Feng, 1992).

However, Ji et al. (1994) found no decrease in membrane permeability for multiple VOCs in the liquid phase (toluene, trichloroethane, methylene chloride) through PDMS; instead, they found that for dilute liquid mixtures, downstream VOC dilution occurred, increasing permeability of all VOCs by increasing the driving force (Ji, 1994b). Similar results are reported for polyurethane and polyether–*block*–polyamides (Ji, 1994a).

Pressure also plays a role in permeability though the picture is not quite clear. Nagai (Nagai, 1994) investigated the permeation properties of brominated PTMSP (Br-PTMSP) and untreated PTMSP above and below the glass-transition temperature. In both regions, for both polymers, permeability decreased with increasing upstream pressure for propane and carbon dioxide. Conversely, Strathmann reports increased permeability through PDMS as upstream pressure increases for octane, toluene, trichloromethane and acetone, up to 10–15 cmHg (Strathmann, 1986).

Membrane-Mediated Absorption

Kamalesh Sirkar's research group has investigated membrane-mediated absorption for VOC removal from gas streams (Poddar, 1996b; Poddar, 1996a, Poddar, 1997). Hollow fibers constructed of microporous,

hydrophobic Celgard™ X-10 polypropylene were used throughout. On the fibers of some of these modules, an ultrathin (approximately 1 μm), plasma-polymerized, nonporous, PDMS coating was placed on the shell side of the fibers (Advanced Membrane Technologies, Inc, Minnetonka, Minn.). A VOC–N₂ gas mixture was pumped through the tube side of the fibers, and an extracting liquid was pumped countercurrently in the shell space. Three absorbents were used; silicone oils 50-cs, 200 (Dow Corning, Midland, Mich.) and a mineral-oil-based fluid, Paratherm NF (Paratherm Corp., Conshohocken, Pa.). The VOC–N₂ mixtures were supplied as standard cylinders (Matheson, E. Rutherford, N.J.) containing relatively high VOC concentrations (993 ppmv acetone, 999 ppmv dichloromethane, 514 ppmv methanol, 236 ppmv toluene). At gas residence times between 1 and 1.5 seconds in uncoated fibers, dichloromethane and toluene exit gas concentrations were lowered to 1–2 ppmv using fresh silicone oil flowing at approximately 5% of the gas flow rate (Poddar, 1996a). Similar performance was achieved using Paratherm NF with toluene, but the silicone oil performance was significantly superior for gas residence times between 0.2 and 0.5 seconds.

Using coated fibers, residence times between 5 and 7 seconds are required to reduce dichloromethane to similar concentrations in the exit gas with fresh silicone oil. However, the difference between Paratherm™ NF and silicone oil is negligible to gas residence times down to a single second. A mixed VOC–N₂ stream was evaluated, with the results summarized in Table A-6. What is obvious is that longer residence times are required for high removal percentage as VOC concentration decreases.

Table A-6 Absorption Data for VOC–N₂ Gas Mixture

VOC feed concentration ppmv		Removal % at given gas contact times	
		17 seconds	5 seconds
Acetone	226	93.8	61.5
Methylene chloride	201	95.5	91.0
Toluene	204	100.0	100.0
Methanol	163	52.7	21.5
Total	794	87.4	70.6

This absorption system was also operated in an absorbent recycle mode with an uncoated hollow-fiber module used to remove VOC from the gas stream (Poddar, 1996b). After extracting VOC from the air, the absorbent flows through the coated, hollow-fiber module membrane operated as a pervaporator. The absorbent then flows into a storage vessel before recirculation through the extracting module. The VOC–N₂ mixtures were supplied in standard cylinders (Matheson, E. Rutherford, N.J.) containing relatively high VOC concentrations (993 ppmv acetone, 999 ppmv dichloromethane, 514 ppmv methanol, 236 ppmv toluene). At gas residence times of 1–1.5 seconds in silicone oil flowing at approximately 5% of the gas flow rate through the extraction module, the dichloromethane exit gas concentration was approximately 50 ppmv and the toluene exit gas concentration was about 25 ppmv (Poddar, 1996b). Comparison of these numbers to the 1–2 ppmv achieved with fresh absorbant indicates that residence times greatly in excess of 1 minute will be required for removal percentages near 90%.

For a given VOC and process condition, silicone oil provided higher removal efficiency than Paratherm™. However, silicone oil exhibits deterioration over an 18 month period causing leakage of the

oil into the gas stream. For that reason, Paratherm™ is the preferred oil for these applications (Poddar, 1996a).

BIOTREATMENT MODULE

Biofouling, in the form of a biofilm colonizing a solid surface, has been a significant problem for many important industrial and medical systems, including water supplies, heat-transfer units, ship hulls, and implanted medical prostheses. To suppress the formation or growth of biofilms in these instances, application of biocides has been the dominant mode of operation. The following review will instead focus on efforts involving reduction of biofouling in biotreatment systems, where the emphasis is on maintenance of an active film, and avoidance of excess biofilm thickness.

Membrane Biofouling

Biological systems for the treatment of contaminated water or gas streams generally involve columns packed with solids operated either as a static or a fluidized bed. The biomass in these systems is generally in the form of a biofilm attached to a solid surface. Excess biomass concentration in the bed retards mass transfer (oxygen, inorganic ions, carbon and energy sources), blocks liquid and gas flow, and generally leads to a loss in reactor productivity. To maintain the reactor activity, two general approaches to prevention of biomass clogging have been evaluated; cleaning and metabolic strategies to suppress biomass growth rate.

Cleaning

Cleaning strategies involve the application of high shear forces or a cleaning treatment to remove a substantial fraction of the biofilm material. These approaches act by disrupting some aspect of the biofilm structure. Characklis (Characklis, 1981) was among the first to characterize the shear stresses (normal and parallel to the surface) that contributed to erosion of biofilms. Rittmann (Rittmann, 1980) developed a series of equations describing the friction factor and resulting shear stresses generated by liquid flow through a packed bed. These equations were modified, using data generated by Characklis, to calculate biofilm loss rates as a function of biofilm thickness, biofilm density, and the shear stress (Rittmann, 1982).

Stress is applied to solid packing to remove unwanted biomass in several different ways. Wubker (Wubker, 1997) used a screw stirrer to periodically mix the polyamide-bead packing within a trickle-bed reactor and found that the amount of biomass removed was directly related to the magnitude of the applied shear stress (stirrer rotation rate) and the total stress applied (stirring time). Daily stirring was sufficient to maintain maximal toluene degradation in this reactor. Taylor et al. (Taylor, 1996) determined that weekly removal, washing, and reinoculation of packing material maximized the productivity of an ethanol fermentation process. Smith et al. (Smith, 1996) determined that the efficient operation of a highly VOC-loaded biofilter could be extended indefinitely if a backwash system that expanded the bed by roughly 40% was used twice weekly. The expansion of the bed led to vigorous mixing of the beads, shearing film from the bead surface. Backwashing, however, is necessarily limited to those biofilters containing packing that can be fluidized.

Weber and Hartmans (Weber, 1996) reported chemical washing of a biotrickling filter. Every two weeks a 0.1M NaOH solution was flushed through the system for 3 hours. Curiously, the toluene removal rate of the bed after the washing was 50% higher than a similar bed that was unwashed. Loss of activity was observed immediately following washing, but recovered to pre-wash levels within 24 hours (Weber, 1996). This approach has significant advantages relative to fluidization, because of its applicability to

beds that are difficult to fluidize and that utilize fluid flow rates much lower than required for fluidization (Cox, 1998).

Biofilm structure can also be disrupted ionically. The extracellular polysaccharide that forms the bulk of the biofilm is crosslinked by divalent cations (primarily Ca^{2+} , to a lesser extent Mg^{2+}). Release of biofilm-bound calcium could lead to biofilm dissolution or detachment from the surface. Gross biofilm detachment was observed by Turakhia (Turakhia, 1983) following exposure of a biofilm to a pulse of a calcium chelating agent, (ethylene glycol)bis(2-aminoethyl ether) (EGTA).

Metabolic strategies

All metabolic strategies are predicated on discovering a nutrient limitation that has a minimal negative effect on biodegradative activity but causes a significant growth rate decrease by increasing the maintenance energy requirement. For example, Schonduve (Schonduve, 1996) determined that while using nitrate as a nitrogen source rather than ammonium caused a noticeable decrease in mixed culture biomass formation rate, the degradation rate was more severely depressed. Smith (Smith, 1996) did find that for a toluene-degrading mixed culture, the use of nitrate in place of ammonium led to a 50% decrease in biomass yield without affecting degradation rates at all.

Addition of 0.4M NaCl led to a 32% greater decrease in biomass formation rate than degradation rate (Schonduve, 1996). Similar results were reported for 30g/L NaCl (Strachan, 1996). Potassium and phosphate limitation were each shown to increase the specific butanol degradation rate of a mixed culture while decreasing the biomass yield by as much as a factor of five (Wubker, 1996), and potassium was shown to increase the specific toluene degradation rate while decreasing the biomass yield (Wubker, 1997).

Figure B-1: AMT Module, Test 1, 0.5 ft^3/min Air, 1.0 L/min Oil, 500 ppm VOCs

Table B-2. AMT Module, Test 2, 0.5 ft³/min Air, 1.0 L/min Oil, 2100 ppm VOCs

Test 2												
Run Date:	4/27/00											
sequence	042700a											
Initial settings:	syringe pump set at 2.0 ml/hr;0.5cfm;temp controller											
	290C;magnehilic (1) rding 1"H2O;magnehelic (2) rding >1"H2O;											
Gen notes	did not experience any software errors during sampling											
	should have adjusted syringe sampling rate to a lower setting (1/4 of what it was set) as a result our numbers are											
	much higher than we expected.

Figure B-8. AMT Module, Test 7, 2.0 ft³/min Air, 0.22 L/min Oil, 170 ppm VOCs

Test #													
36655													
Initial conditions:	magnehelic (1) ~0.9"H ₂ O;magnehelic (2) >1"H ₂ O;ran at 200ppm&4cfm = 4ml/hr and 680;oil pressure 5psi;												
	oil temp 78;temp controller setting 290C;sample flow through rotameter 53;												
Observations:	VOC removal was low during this test run. Recommend changing oil and running at a higher VOC conc-												
	centration.

Test 14												
Run date 6/06/00												
Initial parameters:	syringe set 4.0ml/hr; air 4cfm (1380-1390); sample flow rate 55cc's; injection temp 290C;											
	oil pressure set at 25psi(11.2 at the module);

Table B-17. Two Parallel AMT Modules, Test 20, 16.0 ft³/min Air, 1.0 L/min Oil, 200 ppm VOCs

Test 20													
Run date 6/22/00													
sequence used 062200c													
Initial parameters:													
air velocity 16ml/hr (1657 volts);syringe flow rate 16ml/hr;													
sample flow set at 55 cc's;Mag(1) >4.0"H2O;Mag(2) >1.0"H2O;													
oil pressure at module 11.0psi;system oil pressure ~ 25psi
