A series of controlled laboratory experiments are carried out in dual Teflon chambers to examine the presence of oligomers in secondary organic aerosols (SOA) from hydrocarbon ozonolysis as well as to explore the effect of particle phase acidity on SOA formation. In all seven hydrocarbon systems studied (i.e., α-pinene, cyclohexene, 1-methyl cyclopentene, cycloheptene, 1-methyl cyclohexene, cyclooctene, and terpinolene), oligomers with MW from 250 to 1600 are present in the SOA formed, both in the absence and presence of seed particles and regardless of the seed particle acidity. These oligomers are comparable to, and in some cases, exceed the low molecular weight species (MW < 250) in ion intensities in the ion trap mass spectra, suggesting they may comprise a substantial fraction of the total aerosol mass. It is possible that oligomers are widely present in atmospheric organic aerosols, formed through acid- or base-catalyzed heterogeneous reactions. In addition, as the seed particle acidity increases, larger oligomers are formed more abundantly in the SOA; consequently, the overall SOA yield also increases. This explicit effect of particle phase acidity on the composition and yield of SOA may have important climatic consequences and need to be considered in relevant models.

Introduction

Organic compounds are a major component of atmospheric aerosols and are important contributors to the climate forcing and human health effects of airborne particles (1). A significant fraction of atmospheric organic aerosols are formed through in-situ oxidation of precursor hydrocarbons in the gas phase followed by partitioning of low-volatility products into the aerosol phase (2). These are referred to as secondary organic aerosols (SOA). Recently, higher molecular weight species beyond the first-generation oxidation products have been identified in SOA (3–6). An increase in the yield of SOA formed on acidic seed particles has also been reported (3, 7, 8). In the previous conceptual model for atmospheric formation of SOA (2), once the oxidation products are in the aerosol phase, no further chemical reaction is assumed to occur. However, with aerosol phase reactions occurring as suggested by recent studies, the overall yield of aerosol from precursor oxidation would increase beyond that resulting from pure equilibrium partitioning. The consequence is that the amount of SOA in the atmosphere may substantially exceed that predicted by current models used in global climate assessments (9).

Several fundamental questions arise. What is the increase in SOA yield in the presence of an acidic substrate for precursor hydrocarbons at or near ambient mixing ratios? Is an acidic substrate required for oligomer formation? What is the chemical nature of these oligomers and what reactions produce them? Is oligomer formation the primary cause for the increased yield of SOA formed on more acidic particles? Is there a quantitative relationship among particle phase acidity, oligomer formation and SOA yield? And finally, is oligomer formation in SOA a ubiquitous phenomenon?

Recent work has addressed some of these questions. Kalberer et al. (5) focused on the photolysis of 1,3,5-trimethylbenzene in the absence of seed particles while Tolocka et al. (6) concentrated on the ozonolysis of α-pinene in the presence of acidic inorganic seed particles. Uncertainties still exist when results from different work are compared, such as whether a preexisting, acidic substrate is necessary for oligomer formation. To fully assess the roles of oligomers in SOA formation as well as in the broader atmospheric chemistry, a wide variety of SOA-forming systems need to be studied. This work addresses the above questions through an extensive series of dual-chamber laboratory experiments. We consider the ozonolysis of α-pinene (mixing ratio from 12 to 135 ppb), one of the most common biogenic hydrocarbons, and of six cycloalkenes (i.e., cyclohexene, 1-methyl cyclopentene, cycloheptene, 1-methyl cyclohexene, cyclooctene, and terpinolene; mixing ratio from 25 to 300 ppb), serving as model compounds for many atmospheric hydrocarbons bearing similar molecular skeletons, in the absence or presence of seed particles of controlled acidity. We demonstrate and explain the explicit effect of particle phase acidity on the amounts and composition of SOA formed. Moreover, we find that oligomers are present in each system studied regardless of the initial particle acidity and speculate that oligomer formation is a ubiquitous phenomenon in ambient aerosols. These results have important implications for predicting the amounts and composition of SOA in the atmosphere.

Experimental Section

All experiments were carried out under dark conditions in Caltech’s dual 28 m³ Teflon chambers. In most experiments, seed solutions were first nebulized into the clean chamber to form seed particles (wet seeds for most α-pinene experiments and dry seeds for cycloalkene experiments). To examine the effect of seed particle acidity on SOA formation, we used two “nonacid” seeds, containing either MgSO₄ or (NH₄)₂SO₄, and two “acid” seeds, containing either [MgSO₄·H₂SO₄] or [(NH₄)₂SO₄·H₂SO₄]. The salt-only solutions were 0.03 M each, and acidified solutions contained 0.03 M salt and...
ozonolysis experiments, the pH values for [MgSO4-only] seed extract was then blown dry under a gentle N2 stream and was extracted in HPLC-grade methanol by sonication. The nearly the same elapsed time (5 samples (47 mm Teflo membrane filters) were collected at was accounted for in data analysis. Aerosol loss to the chamber wall was continuously measured. Aerosol number concentration, size distribution, hygroscopic growth, and hydrocarbon mixing ratio were controlled (e.g., at 55% and 20°C for the α-pinene ozonolysis experiments). Relative humidity and temperature were increased from the nonacid to the acid seed in the MgSO4 case. Thermodynamic calculations (10) show that the four seed particles, once stabilized in the chamber, had distinct pH values. For example, at the RH of 55% for α-pinene ozonolysis experiments, the pH values for [MgSO4-only] seed and [MgSO4 + H2SO4] seed were 6.5 and −0.3, respectively.

0.05 M H2SO4. Cyclohexane was then injected to act as a hydroxyl radical scavenger, followed by hydrocarbon and ozone injection. Relative humidity and temperature were controlled (e.g., at 55% and 20°C for the α-pinene ozonolysis experiments). Each filter was extracted in HPLC-grade methanol by sonication. The extract was then blown dry under a gentle N2 stream and reconstituted by an acetic acid solution/methanol mixed solvent. A portion of the filter extract was analyzed by a Hewlett-Packard 1100 series liquid chromatography–mass spectrometry (LC–MS) system to identify and quantify low molecular weight species (MW < 250). Another portion of the filter extract was analyzed by an LCQ classic ion trap mass spectrometer (IT-MS) to identify SOA components with molecular weights ranging from 80 to 1600. Both negative and positive (Na+ added) ion modes of the IT-MS detection were carried out, so that compounds of different acidity and polarity could be detected. In addition, some specific ions were isolated and further fragmented by collision-induced dissociation to produce the so-called tandem MS. Most of the MS/MS in this work were produced under the negative ion mode, since the isolated ions had less interference and the backgrounds were cleaner than the positive ion mode.

We carried out each pair of nonacid and acid experiments in the two chambers in parallel, with all other conditions held identical. Thermodynamic calculations (10) show that the four seed particles, once stabilized in the chamber, had distinct pH values. For example, at the RH of 55% for α-pinene ozonolysis experiments, the pH values for [MgSO4-only] seed and [MgSO4 + H2SO4] seed were 6.5 and −0.3, respectively. The pH values for [(NH4)2SO4-only] seed and [(NH4)2SO4 + H2SO4] seed were 4.6 and 2.4, respectively. The acidity increase from the nonacid to the acid seed in the MgSO4 case exceeded that in the (NH4)2SO4 case by 4.6 pH units.

Results and Discussion

Figure 1 shows the relative yield difference (RYD) of SOA between the acid and nonacid cases for seven pairs of α-pinene ozonolysis experiments on MgSO4 particles, two pairs on (NH4)2SO4 particles, and two pairs of terpinolene ozonolysis experiments on MgSO4 particles. Within the range of α-pinene mixing ratios shown (i.e., 12, 25, 48, 52, 96, 120, and 135 ppb), the absolute SOA yields are 0.30, 0.32, 0.35, 0.38, 0.46, 0.52, and 0.53, respectively, for the nonacid cases and are 0.41, 0.43, 0.44, 0.47, 0.53, 0.57, and 0.57, respectively, for the acid cases.
FIGURE 2. Ion trap mass spectrum (+ ion mode) of the SOA from the ozonolysis of (a) 120 ppb α-pinene on MgSO4-only seed (RH = 55%). In the m/z range up to 1600, the average background ion intensity is ~ 400 000, which is labeled as the dashed line in this and the following MS, unless noted otherwise. See Supporting Information, Figure S3, for a typical background MS. (b) 120 ppb α-pinene on MgSO4-H2SO4 seed. Other experimental conditions are identical to panel a. (c) 72 ppb α-pinene on (NH4)2SO4-only seed. Other experimental conditions are identical to panel a. (d) 72 ppb α-pinene on (NH4)2SO4-H2SO4 seed. Other experimental conditions are identical to panel a.
consistently detected by the IT-MS in the negative ion mode (see Supporting Information, Figure S2). However, negative ions with $m/z$ of 329, 343, 357, 371, and 385 are also detected by the IT-MS (see Supporting Information, Figure S2). The presence of these high MW species is confirmed by the detection of ions with $m/z$ of 353, 367, 381, 395, and 409 in the positive ion mode IT-MS, as shown in Figure 2a. These ions are pseudomolecular ions [M + 23]$^+$, formed by the addition of a Na$^+$ to the neutral molecules. A broad range of compounds can be detected as their Na$^+$ adducts in the positive ion mode IT-MS, thus better reflecting the overall composition of SOA. Figure 2a illustrates that in the SOA formed on the nearly neutral MgSO$_4$ seed, small oligomers (MW from 250 to 450) are the most abundant species. These...
species are separated regularly by mass units such as 14, 16, 18, and 30, which is characteristic of a copolymer system (15), indicating the difference of CH₂, O, and H₂O groups, or a combination of them, among monomers and oligomers. It is striking that the low MW species (MW < 250) comprise only a minor fraction of the total ion signals in the mass spectrum. In previous studies, high MW species may have decomposed during sample preparation or instrumental analyses (such as in a GC oven) (16), resulting in a possible overestimation of low MW species. The IT-MS employs an electrospray ionization source that better preserves molecular integrity by soft ionization (17).

When the seed becomes much more acidic (MgSO₄ - H₂SO₄), as shown in Figure 2b, the resultant SOA comprises many more large oligomers (MW from 450 to 950), most of which have higher ion intensities; thus, mass concentrations of these species exceed, by at least a factor of 2, those in the SOA formed on MgSO₄-only seed. Some even larger oligomers (MW from 950 to 1600) are now detected (with signal-to-noise ratios larger than 3) in the SOA formed on the acidic seed. On the other hand, the mass distribution of small oligomers remains roughly in the same pattern, with a slight decrease in some ion intensities. Similar difference in SOA composition between nonacid and acid MgSO₄ seeds is consistently observed in all other six pairs of experiments on the R-pinene system (see Supporting Information, Figure S4, for detail). Overall, our MS/MS results confirm that oligomers originate from low MW SOA species in all the systems studied. For the R-pinene ozonolysis system, with the monomers having MW centered about 180 (13), the small oligomers (MW from 250 to 450) are likely dimers, whereas the larger oligomers (MW from 450 to 950) are likely trimers, tetramers, and pentamers, consistent with the discussion in Tolocka et al. (6). On the basis of the structures of oligomers and corresponding monomers, we propose three possible reaction pathways in the aerosol phase: aldol reaction between carboxyls, gem–diol reaction between carboxyls with the
participation of a water molecule, and acid dehydration with the loss of a water molecule. The first two reactions have been discussed in some recent work (3, 5-8). All three reactions require acid or base catalysis. Detailed reaction mechanisms are well-established in organic chemistry literature. We note that since many of the low MW SOA species have functional groups in branched positions, the oligomers eventually formed may contain both straight-chain and cross-linked sections.

The SOA composition difference between nonacid and acid cases actually reflects the kinetics of these acid-catalyzed reactions. As seed acidity increases, oligomer formation accelerates, and larger oligomers form within the same experimental time frame than form on less acidic seed. The slight decrease in the ion intensities of some small oligomers, as shown in Figure 2a,b, actually may reflect their transformation into larger oligomers at roughly 5 h from the onset of ozonolysis. In similar experiments on dry (NH₄)₂SO₄ seed, abundant small and large oligomers are detected in SOA from α-pinene ozonolysis, even without H₂SO₄ in the seed, as shown in Figure 4. Apparently, the higher acidity of the dry seed, as compared with the wet seed, facilitates faster formation of large oligomers.

Despite the sensitivity of SOA formation to the particle phase acidity, we find that oligomers (MW from 250 up to 1600) are present in SOA in all the systems studied regardless of the seed pH. As an example of the cycloalkene ozonolysis system, Figure S6 (Supporting Information) shows the presence of oligomers with MW up to 700 (i.e., structurally up to possibly pentamers) in the SOA from cycloheptene ozonolysis. Of particular importance, in the α-pinene ozonolysis system where a variety of seed particles are examined, similar types of oligomers are present in SOA both in the presence and absence of seed particles (see Figure 5 for the latter case). This suggests that organic acids produced from the gas-phase hydrocarbon oxidation itself may actually provide necessary acidity for catalytic reactions. No preexisting, acidic substrate is required for oligomer formation, consistent with the finding by Kalberer et al. (5). Since ambient aerosols tend to be somewhat acidic, we speculate that oligomers are widely present in atmospheric organic aerosols and that they may comprise a substantial fraction of the total aerosol mass. Since the proposed heterogeneous reactions take place readily under base catalysis as well, the ubiquity of oligomers in ambient aerosols appears all the more likely.
