10 **ABSTRACT**

11 The new version of EPA's positive matrix factorization (EPA PMF) software, 5.0, includes three  
12 error estimation (EE) methods for analyzing factor analytic solutions: classical bootstrap (BS),  
13 displacement of factor elements (DISP), and bootstrap enhanced by displacement (BS-DISP).  
14 These methods capture the uncertainty of PMF analyses due to random errors and rotational  
15 ambiguity. To demonstrate the utility of the EE methods, results are presented for three data sets:  
16 (1) speciated PM<sub>2.5</sub> data from a chemical speciation network (CSN) site in Sacramento,  
17 California (2003–2009); (2) trace metal, ammonia, and other species in water quality samples  
18 taken at an inline storage system (ISS) in Milwaukee, Wisconsin (2006); and (3) an organic  
19 aerosol data set from high-resolution aerosol mass spectrometer (HR-AMS) measurements in  
20 Las Vegas, Nevada (January 2008). We present an interpretation of EE diagnostics for these data  
21 sets, results from sensitivity tests of EE diagnostics using additional and fewer factors, and  
22 recommendations for reporting PMF results. BS-DISP and BS are found useful in understanding  
23 the uncertainty of factor profiles; they also suggest if the data are over-fitted by specifying too  
24 many factors. DISP diagnostics were consistently robust, indicating its use for understanding  
25 rotational uncertainty and as a first step in assessing a solution's viability. The uncertainty of  
26 each factor's identifying species is shown to be a useful gauge for evaluating multiple solutions,  
27 e.g., with a different number of factors.

28 **HIGHLIGHTS**

- 29
- We provide examples and interpretation of new error estimation methods in EPA PMF
  - Multiple error estimation methods improve understanding of rotational uncertainty
  - Multiple error estimation methods provide range of uncertainty in factor profiles
- 30
- 31

33 Receptor modeling, air pollution, water pollution, positive matrix factorization, EPA PMF

## 34 **1. INTRODUCTION**

35 Multivariate receptor modeling tools are widely used for examining patterns in environmental  
36 data. Positive matrix factorization (PMF) is one such model and data analysis tool that  
37 decomposes a matrix of speciated sample data into two matrices—factor contributions and factor  
38 profiles—in order to understand the factors or sources impacting the speciated sample data  
39 (Poirot et al., 2001; Paatero et al., 2014; Paatero et al., 2003; Reff et al., 2007; Ulbrich et al.,  
40 2009; Zhang et al., 2011; Hopke, 2008; Kim and Hopke, 2007; McCarthy et al., 2013; Brown et  
41 al., 2012). The two most common PMF programs are PMF2 and ME-2, in addition to EPA PMF,  
42 a freely available graphical user interface (GUI) developed by the U.S. Environmental Protection  
43 Agency (EPA) that uses the ME-2 program. The detailed methods of these programs have been  
44 documented elsewhere (Paatero, 1997; Paatero and Tapper, 1994), and are summarized below.

45 A speciated data set can be viewed as a data matrix  $\mathbf{X}$  of dimensions  $n$  by  $m$ , in which  $n$  samples  
46 and  $m$  chemical species were measured. Rows and columns of  $\mathbf{X}$  and of related matrices are  
47 indexed by  $i$  and  $j$ , respectively. The goal of multivariate receptor modeling, for example with  
48 PMF, is to identify the number of factors  $p$ , the species profile  $f$  of each factor, and the amount of  
49 mass  $g$  contributed by each factor to each individual sample that solve the chemical mass balance  
50 between measured species concentrations and factor profiles (Equation 1):

$$51 \quad x_{ij} = \sum_{k=1}^p g_{ik} f_{kj} + e_{ij} = c_{ij} + e_{ij} \quad (1)$$

52 where  $e_{ij}$  is the residual for each sample/species and  $c_{ij}$  is the modeled solution of  $x_{ij}$ . Entire  
53 matrices are denoted by capital bold-face letters. Columns of the factor contribution matrix  $\mathbf{G}$   
54 may be denoted by  $\mathbf{g}_k$ , and similarly rows of factor profile matrix  $\mathbf{F}$  denoted by  $\mathbf{f}_k$ .

55 In PMF, factor elements are constrained so that no sample can have a significantly negative  
56 contribution. PMF allows each data value to be individually weighted. This feature allows  
57 analysts to adjust the influence of each data point, depending on the confidence in the  
58 measurement. The PMF solution minimizes the object function  $Q$  (Equation 2) via a conjugate

59 gradient algorithm, based upon the estimated data uncertainties (or adjusted data uncertainties)  
60  $u_{ij}$ .

$$61 \quad Q = \sum_{i=1}^n \sum_{j=1}^m \left[ \frac{x_{ij} - \sum_{K=1}^P g_{ik} f_{kj}}{u_{ij}} \right]^2 \quad (2)$$

62 In some scientific disciplines, data rows are normalized (e.g. to sum=1) before the data matrix is  
63 analyzed by PMF models. In such a scaled matrix the errors of data values are not uncorrelated.  
64 However, such normalization does not require any special attention before fitting the data with  
65 PMF: For any row  $i$ , the fitted values  $g_{ik}$  take care of any error in normalization (i.e. of the  
66 correlated part of the error) on row  $i$ , so that fitting the values  $f_{kj}$  only deals with the original  
67 uncorrelated errors.

68 ME-2 is the underlying program used to solve the PMF problem in EPA PMF (Norris et al.,  
69 2014), the GUI that feeds the data and user specifications to ME-2. ME-2 then performs the  
70 iterations via the conjugate gradient algorithm until convergence to a minimum  $Q$  value is  
71 obtained. The minimum  $Q$  may be global or local; users can attempt to determine whether  $Q$   
72 values are global or local by using different starting points for the iterative process and  
73 comparing the minimum  $Q$  values reached. Output from ME-2 is then fed back through EPA  
74 PMF and formatted for users to use and visualize. The latest version of EPA PMF, version 5.0,  
75 includes a revised signal/noise (S/N) calculation and new error estimation (EE) methods. S/N  
76 details are in the EPA PMF Fundamentals and User Guide (Norris et al., 2014), while details of  
77 EE methods are summarized here and presented fully in Paatero et al. (2014). In conjunction  
78 with the new EPA PMF version, this manuscript demonstrates the utility of the multiple EE  
79 methods over multiple case studies (speciated fine particulate matter [PM<sub>2.5</sub>] data from  
80 Sacramento; water quality data from Milwaukee; and high-time-resolution aerosol mass  
81 spectrometer (HR-AMS) data from Las Vegas) and provides recommendations for reporting  
82 PMF results. These case study examples using different ambient data sets are presented to  
83 complement the theory behind new EE methods in EPA PMF and ME-2, and synthetic data  
84 analyses presented in a companion paper (Paatero et al., 2014). Together, they show the use of  
85 multiple EE methods.

86 **2. METHODS**

87 **2.1 Error Estimation in EPA PMF and ME-2**

88 As described in detail in Paatero et al. (2014) variability in the PMF solution has traditionally  
89 been assessed via bootstrapping (BS), where multiple PMF solutions are generated by using a  
90 series of data sets that are resampled versions of the original data set. EPA PMF performs BS by  
91 randomly selecting non-overlapping blocks of consecutive samples (block size is suggested by  
92 the software or by the user) and creating a new input data file of the selected samples, with the  
93 same dimensions (i.e., number of samples and number of species) as the original data set. PMF is  
94 then run on the new resampled data set, and each BS factor is mapped to a base run factor by  
95 comparing factors' contributions (**G** matrix) for those samples included in the resampled data set.  
96 The BS factor is assigned to the base factor with which the BS factor has the highest uncentered  
97 correlation, above a user-specified threshold. If no base factors have a correlation above the  
98 threshold for a given BS factor, that factor is considered “unmapped.” If more than one BS  
99 factor from the same run is correlated with the same base factor, they will all be mapped to that  
100 base factor. This process is repeated for as many BS runs as the user specifies. In this manner, an  
101 understanding of the uncertainty of the apportionment of each species in each factor is found.

102 EPA PMF and ME-2 now have two additional EE methods: displacement (DISP) analysis and  
103 bootstrapping with displacement (BS-DISP). The three methods are complementary and can be  
104 used to understand the uncertainty of a PMF solution:

- 105 1. BS intervals include effects from random errors and partially include effects of rotational  
106 ambiguity. If the user misspecifies data uncertainties, this modeling error usually has  
107 minimal impact in BS results.
- 108 2. DISP intervals include effects of random errors and rotational ambiguity. If the user  
109 specifies too-small data uncertainties, then this modeling error results in DISP intervals  
110 that are too short. Specifying too-large data uncertainties, e.g., when a species is made  
111 weak intentionally, results in DISP intervals that are too long.

112 3. BS-DISP intervals include effects of random errors and rotational ambiguity. If the user  
113 misspecifies data uncertainty, BS-DISP results are more robust than for DISP since the  
114 DISP phase of BS-DISP does not displace as strongly as DISP by itself.

115 With DISP, each fitted element in  $\mathbf{F}$  in the base PMF solution is “displaced” from its fitted value  
116 far enough so that  $Q$  increases by a predetermined amount called  $dQ^{max}$ . Each such extended  
117 displacement is interpreted as the upper or lower interval estimate of the perturbed variable, thus  
118 yielding an uncertainty estimate for each species in each factor profile. The uncertainty estimate  
119 consists of both data uncertainties (data noise) and rotational ambiguity. Depending on the data  
120 set in question, one or the other may be more significant. In EPA PMF, only “strong” species are  
121 actively displaced in DISP. Since “weak” variables have their uncertainty increased by a factor  
122 of 3 and DISP intervals are directly related to species uncertainties, these result in large error  
123 estimates for weak species. Hence, only “strong” species are displaced in DISP.

124 BS-DISP was developed to combine BS’s strength of robustness to data errors and DISP’s  
125 strength of capturing rotational uncertainty. BS-DISP is a combination of BS and DISP methods  
126 in which each resampled data set is decomposed into profile and contribution matrices and then  
127 fitted elements in  $\mathbf{F}$  are displaced. The collection of all results from the process of resampling,  
128 decomposing, and displacing is then summarized to derive uncertainty estimates. Intuitively, this  
129 process may be viewed as follows: each BS resample results in one solution that is randomly  
130 located within the rotationally accessible space. Then, the DISP analysis determines an  
131 approximation for the rotationally accessible space around that solution. Taken together, all the  
132 approximations of rotationally accessible spaces for randomly located solutions represent both  
133 the random uncertainty and the rotational uncertainty for the modeled solution to the complete  
134 data set.

## 135 **2.2 EE Results and Diagnostics in EPA PMF**

136 With three EE methods, there is copious output generated by ME-2 and EPA PMF for evaluating  
137 PMF solutions. In the results presented here, all diagnostics and data are readily available in the  
138 output of EPA PMF. For DISP, the focus is on the number of swaps at the lowest  $dQ^{max}$  level and  
139 the percent change in  $Q$  ( $\%dQ$ ), where swaps occur if factors change so much that they exchange  
140 identities, indicating a “not-well-defined (NWD) solution” (Paatero et al., 2014). In addition, the

141 minimum and maximum values for each species that were reached during displacement for the  
142 lowest  $dQ^{max}$  level are used as the DISP uncertainty range for each factor profile. In DISP, only  
143 “strong” species are used, since DISP is very sensitive to higher data uncertainties, e.g., those  
144 that occur when a user makes a species “weak” in EPA PMF, where data uncertainty is tripled.  
145 With BS, the fraction of BS runs mapped to the base solution by factor is assessed to understand  
146 the reproducibility of the base solution. The 5<sup>th</sup> and 95<sup>th</sup> percentiles are used as the BS  
147 uncertainty range for each factor profile. All species are used in BS, since the input data are  
148 being resampled. BS-DISP diagnostics include the overall fraction of BS-DISP runs that met all  
149 BS-DISP criteria, including factor swaps, decrease in  $Q$ , and lack of mapping via BS. Ideally, the  
150 identifying species for each factor, e.g., silicon and calcium for a soil factor, should be activated  
151 in DISP and BS-DISP. For DISP and BS-DISP, results for actively displaced species are  
152 considered to be the most reliable; other species, left passive in DISP or BS-DISP, may have  
153 error intervals that are smaller than if they were actively displaced.

154 Since species concentrations can often span multiple orders of magnitude, it can be difficult to  
155 compare EE results among solutions or species using concentration units. As presented by  
156 (Paatero et al., 2014), the interval ratio can be used to compare results among species and is  
157 defined as the length of the given species’ EE interval divided by the interval midpoint. With this  
158 method, the maximum interval ratio is 2, and is indicative of more uncertain results. For DISP,  
159 endpoints of the uncertainty interval for a specific **F** factor element are the minimum and  
160 maximum values for that factor element observed in all displacements and are output by ME-2 in  
161 the DISPres file, with one file for each  $dQ^{max}$ . For BS, the endpoints of the uncertainty interval  
162 for a factor element are the 5<sup>th</sup> and 95<sup>th</sup> percentile values for that factor element from all BS  
163 resamples, calculated by EPA PMF using the PMF\_ab\_boot.dat file output from ME-2. For BS-  
164 DISP, each BS resample is displaced and minimum and maximum values are calculated for each  
165 factor element as described for DISP. EPA PMF then calculates the 5<sup>th</sup> percentile of the  
166 minimums and 95<sup>th</sup> percentile of the maximums, which are used as the lower and upper bounds  
167 for BS-DISP EE; the minimums and maximums for each BS-DISP iteration are output by ME-2  
168 in the BSDISPres file, with one file for each  $dQ^{max}$  value. In the examples presented here, the  
169 interval ratios of the identifying species for each factor are compared among species and runs. If  
170 the interval ratios of the identifying species of a given factor are large, the identification of that  
171 factor is more uncertain than factors whose identifying species’ interval ratios are lower.

## 172 2.3 Example Data Sets: Sacramento PM<sub>2.5</sub>, Milwaukee Water, and Las Vegas HR-AMS 173 Data

174 Table 1 summarizes the settings used for EPA PMF analysis for all three data sets presented  
175 here; details for each data set follow the table. Summary statistics of input parameters for each  
176 data set are provided in Supplemental Information. Multiple runs with different numbers of  
177 factors were run for each data set; PMF and EE diagnostics for each run are provided by data set,  
178 including figures showing how factor profiles and EE intervals changed with increasing number  
179 of factors.  $Q_{expected}$  was calculated for each scenario, equal to (number of non-weak data values in  
180  $\mathbf{X}$ ) – (numbers of elements in  $\mathbf{G}$  and  $\mathbf{F}$ , taken together). For example, for five factors, 642  
181 samples, and 19 strong species, this equals  $(642*19) - ((5*642)+(5*19))$ , or 8893. For six  
182 factors,  $Q_{expected}$  would be 8232, and for seven factors it would be 7571. Weak data values were  
183 excluded due to their minor influence on  $Q_{expected}$ .  $Q/Q_{expected}$  was calculated by species, as the  
184 sum of the squared scaled residuals (i.e.,  $Q_{true}$ ) divided by (overall  $Q_{expected}$  divided by number of  
185 non-weak species); the denominator is simply the overall  $Q_{expected}$  divided equally across species.

186 For the Sacramento data set, 24-hour speciated PM<sub>2.5</sub> data for the Del Paso Manor monitoring  
187 site in Sacramento, California, operated as part of the chemical speciation network (CSN), were  
188 downloaded from EPA's Air Quality System (AQS) database, for July 2003 through February  
189 2009. Concentrations and uncertainties were used as reported, to provide an example of using  
190 commonly available data; no censoring of data below detection was done, nor were samples with  
191 missing data included. Supplemental Table 1 provides summary statistics of input data. Nine  
192 aberrant samples, when Fourth of July or New Year's Day fireworks occurred, were excluded,  
193 leaving 642 samples for PMF analysis. The 19 species with S/N greater than 1 were included,  
194 including PM<sub>2.5</sub> mass. For simplicity in this example, no species were made weak. Between five  
195 and seven factors were run.

196 For the Milwaukee data set, water samples of combined sewer outflows (wastewater plus  
197 stormwater), taken from an inline storage system (ISS) in Milwaukee and described in detail in  
198 (Soonthornnonda and Christensen, 2008) and (Bzdusek et al., 2006), were explored; additional  
199 information is available at <http://v3.mmsd.com/wastewatertreatment/deep-tunnel>. Samples were  
200 collected from multiple sites on one day and were analyzed for trace metals (Cd, Cr, Cu, Pb, Ni,  
201 Zn) via EPA method 6010 (Inductively Coupled Plasma-Atomic Emission Spectrometry), and

202 for biological oxygen demand (BOD), total suspended solids (TSS), total phosphorus (TP), and  
203 ammonia (NH<sub>3</sub>) via standard methods (American Public Health Association methods 5210B,  
204 2540D, and EPA methods 365.1 and 350.1). Supplemental Table 2 provides summary statistics  
205 of input data. Ten species across 53 samples were used, with three factors, as described by  
206 Soonthornnonda and Christensen (2008). Since Cd values were one of two values across all  
207 samples, indicating that the concentrations were near or below the detection limit, Cd was made  
208 weak in one run and excluded in another. Active species in BS-DISP were NH<sub>3</sub>, Cr, and TSS.

209 For the Las Vegas data set, HR-AMS measurements were made outdoors next to a classroom and  
210 play yard at Fyfe Elementary School, 18 meters from the US 95 freeway soundwall in Las  
211 Vegas, Nevada, during January 2008. Analysis of these data, including development and  
212 assessment of a PMF solution, are described in Brown et al. (2012). The HR-AMS measures  
213 non-refractory PM<sub>1</sub>, including detailed spectra of organic aerosol (OA), which can then be  
214 decomposed by PMF (Allan et al., 2003; Jayne et al., 2000; Jimenez et al., 2003; DeCarlo et al.,  
215 2006; Ulbrich et al., 2009; Zhang et al., 2011; Lanz et al., 2010). Unlike traditional OA analysis,  
216 where aerosol is collected on filters over the course of many hours and later analyzed for  
217 individual molecules by gas chromatography-mass spectroscopy (GC-MS) or other techniques,  
218 the HR-AMS provides a high-time-resolution quantification of OA via mass spectra. The OA is  
219 characterized by a detailed mass spectrum of individual mass-to-charge ratios  $m/z$ ; a time series  
220 of these mass spectra can then be decomposed via PMF to understand the OA composition (Ng  
221 et al., 2010; Ulbrich et al., 2009; Jimenez et al., 2009). Factors range in both volatility and degree  
222 of oxidation (Donahue et al., 2012; Jimenez et al., 2009; Kroll et al., 2011): low-volatility  
223 oxygenated organic aerosol (LV-OOA), semi-volatile oxygenated organic aerosol (SV-OOA),  
224 hydrocarbon-like organic aerosol (HOA), and biomass burning organic aerosol (BBOA). LV-  
225 OOA is highly oxygenated and is commonly found in all ambient OA; it typically has a high  
226 amount of  $m/z$  44 (COO<sup>+</sup> fragment). HOA is generated by primary emissions, has low oxygen  
227 content, and is typically composed of saturated fragments such as  $m/z$  43 (C<sub>3</sub>H<sub>7</sub><sup>+</sup> fragment) and  
228 55 (C<sub>4</sub>H<sub>7</sub><sup>+</sup> fragment). In between HOA and LV-OOA in terms of oxidation is SV-OOA, which is  
229 composed of a mixture of the fragments in LV-OOA and HOA. BBOA is also somewhere  
230 between HOA and LV-OOA, depending on the combustion conditions (e.g., residential biomass  
231 burning versus wildfires) and aging of the OA, but is associated with  $m/z$  60 (C<sub>2</sub>H<sub>4</sub>O<sub>2</sub><sup>+</sup> fragment),

232 which is derived from and is proportional to the biomass burning tracer molecule levoglucosan  
233 (Alfarra et al., 2007; Canagaratna et al., 2007; Lee et al., 2010).

234 In Brown et al. (2012), results using two-minute averaged data were presented. To reduce ME-2  
235 run time and EPA PMF processing time, 20-minute averaged data were used in this analysis. A  
236 75% completeness requirement was used for each 20-minute average, resulting in 1405 samples  
237 used in EPA PMF. Fragments with S/N less than 5 were made weak, meaning their uncertainties  
238 were increased by a factor of three; of the total 113 fragments ( $m/z$  up to 140), 12 were  
239 downweighted by this scheme. Supplemental Table 3 provides summary statistics of input data.  
240 Results were essentially identical between the two-minute in Brown et al. (2012) and the 20-  
241 minute data set used here, with the correlations ( $r^2$ ) between the factor profiles and factor  
242 contributions of the two data sets ranging between 0.98 and 0.999. EE results for the four-factor  
243 solution presented in Brown et al. (2012), as well as for three and five factors, are discussed here.  
244 No censoring of data below detection or substitution of missing data was done. Active species  
245 for BS-DISP were  $m/z$  43, 44, 55, and 60.

### 246 **3. RESULTS AND DISCUSSION**

#### 247 **3.1 Sacramento PM<sub>2.5</sub> Data**

248 Five to seven factors were used with the Sacramento data; profiles are shown in Figure 1 and  
249 results are summarized in Table 2 and Supplemental Table 4. Profiles identified for the five-  
250 factor solution included: (1) nitrate; (2) chlorine with sodium; (3) sulfate; (4) biomass  
251 burning/potassium (K); and (5) soil (Si, Ca, Fe). Moving to six factors, copper, chromium, and  
252 nickel moved out of the burning and soil factors to a new copper/metals factor. At seven factors,  
253 sodium ion separated from the chlorine factor into its own factor. PM<sub>2.5</sub> mass, ammonium,  
254 elemental carbon (EC), organic carbon (OC), K, Si, sulfate and nitrate were well predicted (i.e.,  
255  $r^2$  observed/predicted greater than 0.8) with five to seven factors. At six factors, iron was better  
256 predicted (0.80 with six factors versus 0.71 with five factors), and at seven factors, aluminum,  
257 calcium, and sodium ion were well predicted. In moving from five to six factors, there was a  
258 decrease in  $Q/Q_{\text{expected}}$  from 5.5 to 4.93, and a smaller decrease when moving from six to  
259 seven factors (4.93 to 4.63). When changes in  $Q$  become small with increasing factors, it can

260 indicate that there may be too many factors being fit, suggesting here that six factors may be the  
261 optimal solution.

262 With five factors, all factors but Cl were mapped in 100% of BS runs (Cl was mapped 86% of  
263 runs), there were no swaps with DISP, and 100% of the BS-DISP runs were successful. Results  
264 were generally stable at six factors as well, with all factors mapped in BS in 100% of runs except  
265 for the copper/metals factor (mapped on 88% of runs). No swaps occurred with DISP, and all  
266 BS-DISP runs were successful. At seven factors, the solution was less stable. The new sodium  
267 factor was mapped with BS in 72% of the runs and copper/metals in 78% of the runs, while other  
268 factors were mapped in 100% of runs. There were no swaps in DISP, but 28% of BS-DISP runs  
269 were rejected due to factor swaps. Thus, while additional species had better observed/predicted  
270 diagnostics with seven factors, these additional factors appeared less stable than the factors found  
271 in the five- and six-factor solutions.

272 As seen in Supplemental Table 4 and Figure 2, DISP error estimate intervals, expressed as  
273 interval ratios to be comparable across species of differing magnitudes, are quite low for key  
274 species, indicating little rotational ambiguity in the solutions. Ratios are generally highest for the  
275 model with seven factors, indicating modestly higher uncertainty for these key species with  
276 seven factors. For BS, interval ratios are generally consistent for a given factor for all three  
277 model runs, with the exception of the copper/metals factor at seven factors. Here, the BS interval  
278 of copper is relatively large, spanning an order of magnitude (0.00012 to 0.0065  $\mu\text{g}$  between the  
279 5<sup>th</sup> and 95<sup>th</sup> BS percentiles), resulting in a very high EE for copper in this factor, which suggests  
280 a poorly defined factor. The BS mapping indicates some instability in the chlorine factor at five  
281 factors, the copper/metals factor at both six and seven factors, and modest instability of the  
282 sodium-only factor with seven factors. The instability of the chlorine, copper/metals, and sodium  
283 factors are further seen with BS-DISP, where the interval ratios for the key species are high for  
284 factors with low BS mapping (chlorine at five factors, copper at six factors, and both sodium and  
285 copper at seven factors). In these three cases, BS-DISP interval ratios approach or are equal to  
286 two, since the BS-DISP 5<sup>th</sup> percentile for these species/factor combinations is at or near zero.  
287 The combination of poor BS mapping of two of seven factors, the very high EE intervals from  
288 both BS and BS-DISP for both copper and sodium factors, and the small change in  $Q/Q_{\text{expected}}$

289 going from six to seven modelled factors indicate that the seven-factor solution is not stable and  
290 likely should not be used.

### 291 **3.2 Milwaukee Water Results**

292 As further described by Soonthornnonda and Christensen (2008), three factors were determined:  
293 (1) stormwater was characterized by high amounts of TSS and Pb; (2) sanitary sewage was  
294 characterized by high BOD, TP, and ammonia; and (3) high-metals-content stormwater, likely  
295 from sewer sediment erosion, was characterized by high concentrations of metals such as Cr.  
296 Table 3, Supplemental Table 5 and Figures 3 and 4 summarize the results. With three factors and  
297 Cd included as weak, all species were relatively well predicted, with  $Q/Q_{expected}$  values all less  
298 than 2 except for BOD. BS results showed 100% mapping for two factors and 86% mapping for  
299 the trace metals factor; DISP had no swaps and 98% of BS-DISP cases were successful. Upon  
300 removing Cd, other species were not any better predicted,  $Q/Q_{expected}$  was similar, and BS  
301 mapping was poorer compared to the run with Cd included (BS mapping 72% for metals factor).  
302 In both scenarios, the poorer BS mapping of the metals factors is likely due to its more  
303 intermittent signal across the samples, relative to the other two more consistent sources. In  
304 addition, the small overall size of the matrix (10 species, 53 samples) is likely at the extreme  
305 lower end of a viable size for PMF applications, which may lead to some instability. Despite  
306 these limitations, the factors when including Cd are stable and as reported by Soonthornnonda  
307 and Christensen (2008), also compare very well with chemical mass balance (CMB) results,  
308 further solidifying their interpretability.

### 309 **3.3 Las Vegas HR-AMS Results**

310 As described by Brown et al. (2012), four factors were determined: LV-OOA, HOA, SV-OOA  
311 and BBOA. On average, HOA made up 28% of the organic matter (OM), had an abundance of  
312  $m/z$  43, and peaked during the morning and evening commute periods coincident with peak  
313 traffic volume. LV-OOA, indicated by an abundance of  $m/z$  44, was highest in the afternoon and  
314 accounted for 25% of the OM. BBOA occurred in the evening hours, was predominantly from  
315 the residential area to the north, and on average constituted 10% of the OM. SV-OOA accounted  
316 for the remaining 37% of the OM, and had an abundance of  $m/z$  57 and 55. The HOA and  
317 LV-OOA factors were nearly identical to those found in other studies; correlations of the profiles

318 with Pittsburgh factor profiles (Ulbrich et al., 2009) were 0.99. The HOA factor profile is very  
319 similar to pure diesel exhaust (Mohr et al., 2009). The BBOA factor had typical tracer fragments  
320 of  $m/z$  60 and 73, which are produced during AMS analysis of levoglucosan and related  
321 anhydrosugars produced during biomass combustion (Lanz et al., 2008; Lee et al., 2010). The  
322 SV-OOA factor profile was similar to that of aged diesel exhaust (Sage et al., 2008).

323 Factor profiles are shown in Figure 5 and EE diagnostics are summarized in Table 4,  
324 Supplemental Table 6, and in Figure 6. For the four-factor base solution, BS resamples  
325 reproduced 100% of the base factors. There were no factor swaps with DISP and, as also seen in  
326 the other data set examples, only an extremely low change in  $Q$  (less than 0.1%) was observed.  
327 However, in BS-DISP, 46% of the runs had swaps. BS-DISP interval ratios were also the largest  
328 among EE methods. The BS-DISP interval ratio was highest for SV-OOA across all EE methods.  
329 These results suggest that the SV-OOA factor is more uncertain than the other factors.

330 With three factors, only HOA, LV-OOA and BBOA were identified, 100% of the BS resamples  
331 identified these 3 factors, 100% of the BS-DISP runs were accepted, and no swaps occurred with  
332 DISP. EE interval ratios are generally lower with three factors than with four factors, with the  
333 exception of DISP interval ratios that were higher when using three instead of four factors. This  
334 may indicate that using three factors distorts the solution so that the three factors also  
335 accommodate parts of the omitted fourth factor SV-OOA. When four factors are used, DISP  
336 intervals are smaller and BS results similar, suggesting at least four factors are needed, despite  
337 the modest BS-DISP results.

338 With five factors, an additional “night OA” factor is found that occurs on most evenings  
339 coincident with BBOA and SV-OOA. However, this night OA factor is only found with 80% of  
340 the BS resamples, while the other factors are mapped in 100% of the runs. With BS-DISP and  
341 five factors, 44% of the runs were accepted and there were no swaps with DISP. These results  
342 indicate that the five-factor solution, and in particular the night OA factor, is much less certain  
343 than the four-factor solution. The modest BS-DISP results with four factors suggest that there is  
344 some factor interdependence and rotational ambiguity, confirmed by the oblique, slanting edges  
345 seen in the G-space plots (Paatero et al., 2005; Paatero et al., 2002). In these results, the oblique  
346 edges in the G-space plots could not be straightened out by applying customary rotational

347 techniques, e.g., by applying Fpeak or by pulling points along the edges. Thus, they indicate a  
348 “modeling error” in the analysis, such as variation in true source profiles during the monitoring  
349 campaign, or presence of data outliers that block the rotations that would be needed for  
350 straightening the edges.

### 351 **3.4 Discussion**

352 In all three data sets, there were no swaps evident in DISP, indicating that the solutions had no or  
353 few data errors and were well defined. These results differ from the synthetic data analyses  
354 shown in Paatero et al. (2014), which did have swaps in DISP but only when there were too  
355 many factors. In the ambient data examples here, even when pushed up to two or more factors  
356 above the “base” solution, swaps did not occur with DISP. This was also the case when small  
357 data sets were run, e.g., the Milwaukee water data. It seems likely that if more than a few swaps  
358 occur with an ambient data set, then there are either too many factors used or that the solution is  
359 not well defined. Thus, DISP appears to be a good first-step screening tool for a PMF solution; if  
360 zero or only a few swaps occur, the user is assured that they are working towards a reasonable  
361 solution, though results with BS and BS-DISP may eventually suggest otherwise.

362 In the examples presented here, BS continues to be a useful EE method even though it does not  
363 account for rotational ambiguity. When factors are not reproduced during BS resampling, it  
364 indicates potential problems with that solution. It could be that too many factors are being used,  
365 as is likely at seven factors in Sacramento PM<sub>2.5</sub> or five factors in Las Vegas HR-AMS data, or  
366 that the factors with low reproducibility occur infrequently in the data. In the case where it is  
367 clear that the occurrence of a factor is dependent on other environmental conditions, such as  
368 wind direction, meteorology, or source operations, it is not surprising that many BS resamples do  
369 not identify that factor. BS results thus are useful for quantifying the uncertainty of a solution,  
370 and also for identifying factors that have a low degree of reproducibility. Such factors with low  
371 reproducibility may still be real, but require additional investigation and support for their  
372 inclusion.

373 BS-DISP combines BS’s strength with data errors and DISP’s strength with rotational  
374 uncertainty. In these examples, solutions with no swaps in DISP and more than 95%  
375 reproducibility with BS had variable BS-DISP results. For example, the four-factor solution with

376 Las Vegas HR-AMS had no swaps in DISP, high reproducibility with BS, and low interval ratios  
377 for the identifying species in each factor. However, there were swaps in 46% of the BS-DISP  
378 runs, indicating some uncertainty with the solution. With positive BS and DISP results and clear  
379 interpretability of the factors, this amount of swaps is not fatal to the analysis, but confirms that  
380 there is some uncertainty in the solution, particularly regarding the SV-OOA factor. Since SV-  
381 OOA factors can vary widely across studies depending on the atmospheric conditions and  
382 processing of OA, and the factors span a much larger range of volatility compared to HOA and  
383 LV-OOA, the modest swapping in BS-DISP appears to confirm its larger uncertainty compared  
384 to other factors.

385 DISP and BS-DISP provide results for four different  $dQ^{max}$  values; the range of results for each  
386 key species/factor combination by  $dQ^{max}$  value can indicate whether uncertainties are controlled  
387 more by rotational uncertainty or user-specified data uncertainties. Supplemental Table 7 shows  
388 the DISP intervals for the Sacramento example for key identifying species in each solution. The  
389 Sacramento example is particularly useful, because the solutions have residuals far exceeding the  
390 input uncertainties and thus have a relatively high  $Q/Q(expected)$ , indicating that the input  
391 uncertainties are not accurate, the factor profiles vary over time, or both. How DISP intervals  
392 change with  $dQ^{max}$  may help explain the high  $Q/Q(expected)$  values. With five factors, nitrate  
393 intervals are nearly independent of  $dQ^{max}$ ; thus, the input uncertainties for nitrate are well  
394 represented by the solution, so that the DISP intervals are controlled predominantly by rotational  
395 uncertainty, i.e., how far rotations may proceed during DISP. In contrast, sulfate, Cl, and Si  
396 intervals increase proportionally to the square of  $dQ^{max}$ , meaning that they double as  $dQ^{max}$   
397 increases by a factor of 4. Thus, there is less rotational uncertainty for these factors; rather, the  
398 uncertainty is due to input uncertainty. At six factors, all species except Cl have intervals that do  
399 not increase proportional to  $dQ^{max}$ , indicating significant rotational uncertainty. With seven  
400 factors, rotational uncertainty appears to be reduced, but at the expense of much larger  
401 uncertainty intervals. These variations in results by  $dQ^{max}$  further support the earlier  
402 interpretation that seven factors are likely too many, and that there are some trade-offs in  
403 uncertainty between the five- and six-factor solutions.

404

#### 405 4. PMF REPORTING RECOMMENDATIONS

406 PMF analyses involve many details about the development of the data, decisions of what data to  
407 include/exclude, determination of a solution, and evaluation of robustness of that solution;  
408 reporting of PMF solutions and analyses vary widely. In many cases, limitations on word count  
409 and other restrictions mean that authors do not include important details of their modeling efforts  
410 in published articles. As more journals publish online and allow appendices or supplemental  
411 material, more analysis details can be shared. Having a consistent base of what is reported will  
412 help all PMF users evaluate, compare, understand, and reproduce PMF analyses. Below, we  
413 provide a sample list of recommended items to report when presenting a PMF analysis. This is  
414 complementary to the AMS-specific strategy recently assembled in (Crippa et al., 2013).

415 *Q values.* Report the  $Q(\text{robust})$  and  $Q(\text{true})$  values of the analysis that was deemed most useful,  
416 and note how  $Q$  or  $Q/Q(\text{expected})$  changed under different scenarios, e.g., with a different  
417 number of factors or with different species included/excluded. Discussion of the obtained  $Q$   
418 value is moot if uncertainties of the input data have been fine-tuned in order to produce  
419 meaningful scaled residuals. In contrast, observing changes in  $Q$  under different scenarios is  
420 often very helpful when selecting between different modeling alternatives, such as different  
421 numbers of factors. When changes in  $Q$  become small with increasing factors, it can be  
422 indicative that there may be too many factors being fit.

423  $Q(\text{expected})$  should also be calculated, but only the “good” or non-weak variables should be  
424 taken into account. The expected value of  $Q$  is approximately = (number of non-weak data  
425 values in  $\mathbf{X}$ ) – (numbers of elements in  $\mathbf{G}$  and  $\mathbf{F}$ , taken together). A downweighted weak variable  
426 has only a small, rarely significant contribution to  $Q(\text{expected})$ , and for simplicity is excluded  
427 here. If the  $Q$  value of the chosen model differs significantly from what is expected (e.g., by a  
428 factor of ten or more), then DISP error analysis becomes invalid and BS-DISP is likely  
429 questionable.

430 Lastly, it can be useful to report if an individual column or row of  $\mathbf{X}$  had a  $Q/Q(\text{expected})$  ratio  
431 that was much higher than that of other columns or rows. This indicates that the column or row  
432 was not well fitted and contributes significantly more than expected to  $Q$ .

433 *Estimated or adjusted uncertainties of input data.* Uncertainties drive not only a base solution  
434 but also the BS, and in particular, the DISP and BS-DISP results. Their development and use in  
435 the PMF analysis needs to be clearly documented. This also includes documenting if extra  
436 modeling uncertainty (an adjustable parameter within PMF) was applied in the analysis.

437 *Lower limit for G (contributions).* In EPA PMF, the lower limit of the normalized contributions  
438 is set to -0.2, since allowing a small negative value helps PMF accept true rotations even in the  
439 presence of a large number of zero values in some G factors.

440 *Use of robust mode.* In EPA PMF, the robust mode is always used, which automatically  
441 downweights by a factor of four the influence of observations that have a scaled residual greater  
442 than 4. Nevertheless, use of robust mode should always be documented in publications.

443 *Treatment of missing values.* If missing data were included in the PMF analysis, they need to be  
444 treated appropriately so they do not influence the solution. Often, the median concentration of a  
445 given species is used, with an uncertainty of four times the median. The scaled residuals for these  
446 points should be inspected to ensure that they are clearly less than one. If missing data are given  
447 a standard deviation of four times the median, then the scaled residuals for these points may  
448 occasionally violate this requirement. In such cases, the analysis should be repeated so that  
449 uncertainties of missing values are increased sufficiently. Multiple statistical methods exist for  
450 replacing missing data with statistically viable values. We do not recommend these methods for  
451 PMF analyses. They are necessary for any statistical procedures that cannot accommodate  
452 missing data. With PMF analyses, inputting a sufficiently large uncertainty makes the data truly  
453 "missing", a process that cannot be improved by using data substitutions. PMF can even be used  
454 to obtain substitution values to be used in other statistical procedures: run PMF so that the values  
455 in question (missing and/or BDL values) have sufficiently large uncertainty values associated to  
456 them. Use the fitted values (fitted by PMF to missing/BDL positions) as substitution values, and  
457 then use them as replacements to whatever values were originally present in the missing/BDL  
458 positions of the matrix.

459 *Treatment of data below detection.* In many published PMF studies, below detection level (BDL)  
460 data values have been censored, i.e., substituted by replacement values, such as  $0.5 \times$  detection  
461 limit, even if the original measured values have been available. It appears that this practice has

462 no proven advantages when species with low S/N are downweighted. On the other hand, it may  
463 be demonstrated that the substitution practice prevents uncertainty estimation, introduces hard-  
464 to-estimate bias, and occasionally gives rise to ghost factors. In general, it is a modeling error if  
465 BDL values are replaced by a fraction of the detection limit. If such a replacement has been  
466 done, then EE of PMF results should not be attempted because none of the available EE methods  
467 is able to estimate the bias error incurred in results by censoring BDL values. If EE is  
468 nevertheless attempted in the presence of such censoring, then a clear warning about  
469 questionable validity of quoted error estimates must be included in the paper. Instead of  
470 substitution methods, PMF modeling using ME-2 directly can be optimized by applying a  
471 specific error model code to censored data values (Paatero, 2000). In this way the known  
472 information, e.g., that a measurement is somewhere between zero and the detection limit, can be  
473 conveyed to ME-2 without any substitutions that would likely bias the results.

474 *Treatment of data equal to or below zero.* Data equal to or less than zero can be included in the  
475 PMF model and, if these values are genuine measured values, should not be censored by  
476 truncation to zero or transformed to positive values. If such censored values must be used  
477 because the original measured values have been discarded, then a warning must be included in  
478 the documentation. EPA PMF allows negative concentration values to be used, though input  
479 uncertainties must still be positive.

480 *Treatment of “total mass.”* In the Sacramento example, uncertainties for total PM<sub>2.5</sub> mass were  
481 used as reported, rather than being further downweighted (e.g., (Reff et al., 2007); (Kim et al.,  
482 2005)). PM<sub>2.5</sub> mass should be downweighted if there are likely significant measurement artifacts,  
483 e.g., gaseous species adsorbing onto filters, or if there are sources that may emit PM<sub>2.5</sub> mass but  
484 none of the measured species, in which case a factor containing only mass could be determined.  
485 In these cases, the inclusion of “full strength” total mass does not help in interpretation of  
486 solutions, and could lead to erroneous results.

487 *Use of constraints.* EPA PMF and ME-2 allow users to constrain or “pull” elements in their  
488 solution. One common reason for pulling is the attempt to align an oblique “edge” in G-space  
489 plots. However, an oblique edge may sometimes be justified because factors in atmospheric or  
490 environmental data are rarely truly independent. Thus pulling contributions based on G-space

491 plots must be clearly justifiable, and should be justified and reported in detail if done. If source  
492 profiles or contributions are known for some factors or samples, and constraints are used to  
493 model these, then this information and the reason (e.g., the industrial plant was shut down and  
494 should have a contribution of zero) should be noted.

495 *BS*. Report the number of resamples analyzed and the size of percentiles of the obtained  
496 distribution of results chosen for error limits, e.g., in EPA PMF these are the 5<sup>th</sup> and 95<sup>th</sup>  
497 percentiles. Also report the percentage of BS factors assigned to each base case factor and the  
498 number of BS factors not assigned to any base case factor, and the interval ratios of each factors'  
499 identifying species.

500 *DISP*. Report species not displaced, such as those downweighted (in EPA PMF, all strong  
501 species are used in DISP), the decrease in  $Q$ , the number of factor swaps, and the interval ratios  
502 of each factors' identifying species. If factor swaps occur for the smallest  $dQ^{max}$ , it indicates that  
503 there is significant rotational ambiguity and that the solution is not sufficiently robust to be used.  
504 If the decrease in  $Q$  is greater than 1%, it is likely the case that no DISP results should be  
505 published unless DISP analysis is redone after finding the true global minimum of  $Q$ .

506 *BS-DISP*. As with BS and DISP, report the number of BS resamples analyzed, the size of  
507 percentiles chosen for error limits (in EPA PMF, these are the 5<sup>th</sup> and 95<sup>th</sup>), the species actively  
508 displaced, the decrease in  $Q$ , and the number of factor swaps. For each factor's identifying  
509 species, note the extent of the EE interval.

## 510 **5. CONCLUSIONS**

511 These examples using different ambient data sets are presented to complement the theory behind  
512 new EE methods in EPA PMF and ME-2, as well as synthetic data analyses presented in a  
513 companion paper (Paatero et al., 2014). Together, they show the use of multiple EE methods.  
514 With these ambient data sets, DISP typically had tight intervals and no factor swaps; it appears  
515 that DISP is a good screening tool for solutions, as solutions that have swaps likely have  
516 significant rotational ambiguity and should probably not be used. BS results do not typically  
517 capture rotational ambiguity, but can help identify factors that are not very reproducible, though  
518 low reproducibility may be due to other influences such as wind direction, source activity, etc.,

519 rather than a poor solution. BS-DISP may yield factor swaps even if BS and DISP diagnostics  
520 are positive, and can be used to identify which factors are more certain than others. One  
521 drawback of BS-DISP is its computation time. A large run (e.g., thousands of samples and a  
522 hundred species) may take tens of hours on a modern PC. Future work may need to focus on  
523 optimization of the algorithms in ME-2 to help significantly decrease the run time.

524 Based on the results here and in Paatero et al. (2014) the different roles of DISP on one hand,  
525 and BS and BS-DISP on the other hand, may tentatively be described as follows: DISP analyzes  
526 the given data set “as is,” not speculating about the reproducibility of the results in future similar  
527 measurements. Hence, uncertainty intervals given by DISP are rather short. The BS-based  
528 methods are based on resampling. Hence, they also estimate variability that follows if a few key  
529 samples are omitted from the data set. Such estimation may be relevant in predicting what might  
530 happen with the following year’s data. A few key samples might not occur at all, or they might  
531 not occur on days when sampling is performed. BS takes into account this kind of uncertainty,  
532 which is not considered by pure DISP. Thus, uncertainty estimates based on BS may be much  
533 larger for such data sets, where a few matrix rows have special importance regarding rotations or  
534 regarding sources that are only observed in a small fraction of all samples.

535 For all EE methods, the interval ratio of each factor’s identifying species can provide an  
536 understanding of the relative certainty of each factor’s identity. However, each data set is unique,  
537 so results will vary. It must be emphasized that, in some cases, a satisfactory analysis cannot be  
538 performed with any number of factors. The following contrived example illustrates this situation.  
539 With four factors, the result is rotationally unique and all three EE methods indicate small  
540 uncertainties. However, with four factors, the fit is not satisfactory as indicated, e.g., by poor  
541 total mass reconstruction, by poor factor interpretability, etc. With five factors, fit is good but  
542 rotational uncertainty is very large and/or there are frequent factor swaps between factors four  
543 and five. What should the scientist do in this situation? It would be wrong to only report either  
544 the four-factor or the five-factor results while ignoring the presence of the alternative solution.  
545 The information in the data set confirms that four factors are not enough. However, the  
546 information is not sufficient for quantitative determination of five factors. If additional  
547 information cannot be inserted for obtaining rotational uniqueness, then the two sets of  
548 inconclusive results (using four and five factors, respectively), as well as the impact of

549 subtracting or adding a factor has on the profiles, contributions, and EE results, should be  
550 reported.

551 The conclusions presented in this work are based on our experience with a limited number of  
552 synthetic and real data sets. It was not our intention to “prove” the validity or usefulness of these  
553 methods. The statistical properties of real data are so unknown and varied that a general  
554 assessment of the validity can only be reached through a long process. Successful and failed  
555 analyses of different data should be carefully reported in literature. Thus, the present conclusions  
556 should not be regarded as the final truth about EE of bilinear models. Instead, these results are  
557 the first steps toward full understanding of these complicated questions. It is essential that  
558 follow-up studies be performed with an open mind, so that general validity of our conclusions is  
559 not taken for granted in all possible situations. Lastly, we provide a recommended “best  
560 practices” list of information for users to report in their publications, which is critical as more  
561 users employ the new EE methods available in ME-2 and EPA PMF.

## 562 **6. DISCLAIMER**

563 The United States Environmental Protection Agency through its Office of Research and  
564 Development funded and collaborated in the research described here under contract EP-D-09-  
565 097 to Sonoma Technology, Inc. It has been subjected to Agency review and approved for  
566 publication.

## Supplemental Information

### Revised Signal/Noise Calculation in EPA PMF

The signal/noise (S/N) calculation in EPA PMF has been revised for version 5.0. Previously, S/N of a given species was essentially the sum of the concentration values divided by the sum of the uncertainty values. While reasonable, this could lead to different problems in certain specific situations. Artificially high S/N values would be obtained in species with a handful of high concentration events, resulting in an S/N that may actually be higher than another species' S/N with a more consistent signal. More seriously, artificially low S/N values could appear for species with a few missing values. Missing values are usually downweighted by very large uncertainty values, typically (much) larger than the largest concentration values in the species in question. If uncertainties for missing values were inflated prior to input into EPA PMF, such inflated uncertainty values will inflate the noise in S/N calculations, resulting in an S/N that actually will be small enough to cause the classification of a strong variable as “weak.” The latter problem has repeatedly been observed in practical work. In addition, the presence of slightly negative concentration values, not uncommon in environmental data, could artificially decrease S and hence the S/N of a species.

In the revised calculation, only concentration values that exceed their uncertainty contribute to the signal portion of the S/N calculation, since the concentration value is essentially equal to the sum of signal and noise, and therefore signal is the difference between concentration and uncertainty.

Two calculations are performed to determine S/N, where concentrations that are below uncertainty are determined to have no signal, and for concentrations above uncertainty, the difference between concentration ( $x_{ij}$ ) and uncertainty ( $s_{ij}$ ) is used as the signal:

$$d_{ij} = \begin{cases} \left( \frac{x_{ij} - s_{ij}}{s_{ij}} \right) & \text{if } x_{ij} > s_{ij} \\ 0 & \text{if } x_{ij} \leq s_{ij} \end{cases} \quad (3)$$

S/N is then calculated as:

$$\left( \frac{S}{N} \right)_j = 1/n \sum_{i=1}^n d_{ij} \quad (4)$$

The result with this new S/N calculation is that species with concentrations always below their uncertainties have an S/N of 0. Species with concentrations that are twice their uncertainty values have an S/N of 1. An S/N greater than 1 often indicates a species with “good” signal, though this depends on how uncertainties are determined. Negative concentration values do not

contribute to the S/N, and species with a handful of high concentration events will not have artificially high S/N. While there are many methods to determine S/N, the one selected in the new version of EPA PMF may be more useful in environmental data analysis compared to the prior version, with the caveat that the S/N is merely one of many analyses for screening data. All S/N values reported in this paper are calculated according to equations (3) and (4).

## Input Data Summary Statistics

Supplemental Table 1. Summary of Sacramento PM<sub>2.5</sub> input data. Concentration units in µg/m<sup>3</sup>.

| Species           | Category | S/N  | Min     | 25th      | Median   | 75th      |
